Preface

This report presents detailed results of Phase III sampling and summaries of Phase I and Phase II sampling for the Richard B. Russell Fish Entrainment Study as required by amendment dated 3 April 1992 to the original Consent Order from the United States District Court for the District of South Carolina signed on 6 December 1991. Phase III data presented in this report include: 1. pumped storage fish entrainment sampling using full (entire intake plume is netted) or partial (approximately 50 percent of the intake plume is netted) recovery nets; 2. summaries of conventional netting results obtained prior to collection of Phase III data; 3. supporting studies such as recovery net calibration and fish mortality testing; 4. results of calibration for fixed-aspect hydroacoustics sampling of fish entrainment; 5. ichthyoplankton entrainment; 6. summaries of baseline data collection; 7. population estimates for threadfin shad and blueback herring; 8. risk assessment of pumped storage operation using population modeling; 9. mobile hydroacoustics summaries; 10. commercial and sport harvest; 11. predictions of future entrainment; 12. summary water quality impacts on striped bass.

This report was prepared by the Environmental Laboratory (EL) of the U.S. Army Engineer Waterways Experiment Station (WES), Vicksburg, MS; AScl, Trotters Shoals Research Facility, Calhoun Falls, SC; the National Biological Survey Fish and Wildlife Cooperative Research Unit (Coop Unit) at the University of Georgia, Athens, GA, Aquacoustics, Inc., and U.S. Army Engineer District, Savannah. The report was prepared for the U.S. Army Engineer District, Savannah, as part of the Richard B. Russell Fish Entrainment Study.

The authors of this report are Dr. John M. Nestler of the Water Quality and Contaminant Modeling Branch (WQCMB), Environmental Processes and Effects Division, (EPED), EL, WES; Messrs. Don Dennerline and Mark Weiland of the Coop Unit, Mr. Gary Weeks of AScl, Mr. Don Degan and Ms. Sandra Howie of Aquacoustics, Inc., and Mr. Jamie Sykes of Savannah District. The report was prepared under the direct supervision of Dr. Mark Dortch, Chief, WQCMB, and under the general supervision of Dr. Richard Price, Chief, EPED, and Dr. John Harrison, Director, EL. Technical reviews by Mr. Tom Cole of WES, and Ms. Toni Schneider of WES are appreciated.

At the time of publication of this report, Director of WES was Dr. Robert W. Whalin. Commander of WES was COL Robin R. Cababa, EN.

This report should be cited as follows:

Executive Summary

Background

The U.S. Army Engineer District, Savannah, operates Richard B. Russell (RBR) Dam and Lake which is located on the Savannah River approximately 16 miles southeast of Elberton, Georgia. RBR Lake is located between two other Federal projects; Hartwell Dam and Lake on the upstream side, and J. Strom Thurmond (JST) Dam and Lake on the downstream side. The RBR powerhouse contains four conventional generation units, and four reversible pump-turbines. The pump-turbines can be used to generate power, or they can be reversed and used as pumps to move water from JST Lake to RBR Lake during periods of low power demand to replenish upstream storage for subsequent peak generation needs.

Potential environmental concerns associated with pump storage include entrainment of fish from the afterbay (JST Lake) during pumping, an increase in entrainment of fish from the forebay (RBR Lake) during generation resulting from generating with eight units versus four, and changes in the water quality regime of both RBR and JST Lakes.

In view of these potential environmental concerns, the Savannah District initiated an exhaustive study in 1986, the Richard B. Russell Fish Entrainment Study. The major objectives of this study were to provide baseline data on the fish community of JST Lake, predict entrainment and fish mortality, develop fish protection measures, and monitor entrainment through the units. Ongoing water quality studies in JST and RBR Lakes were modified and expanded to supplement the fishery studies and address water quality concerns. No study identified any factor which indicated that commercial operation of the pumpback units at RBR would produce irreparable impacts to the aquatic ecosystems at RBR and JST Lakes.

Testing and Monitoring Plan

The initial results of the above studies were presented in a Final Supplement to Final Environmental Impact Statement on Pump Storage in July 1991. This

document presented the study data, results of various modeling efforts to address fish entrainment and water quality in JST and RBR Lakes, results of various fish protection investigations, and entrainment predictions based on the study results. This document recommended a phased approach for bringing the pump-turbines into operation involving extensive testing and monitoring. The document became the basis for the development of the RBR Testing and Monitoring Plan (T&MP). The general study design and conduct of the T&MP is described in a Consent Order granted by the Charleston, SC United States District Court on December 6, 1991. An amendment (April 3, 1992) to this Consent Order required the Corps of Engineers conduct specific tests and studies to complete mechanical and environmental testing of the units. The T&MP was attached to this amendment and described the specific studies to be conducted and their timing. The T&MP identifies all environmental concerns and describes both water quality and fishery studies that the Corps of Engineers, State of South Carolina, State of Georgia, U.S. Fish and Wildlife Service, and the National Wildlife Federation felt were required to quantify the impacts of operating the pumpback units on RBR and JST Lakes. All studies were conducted to be consistent with the following four general provisions of the T&MP:

- a. A phased approach for bringing the units into operation which provides for a period of testing the units prior to committing them for dependable, commercial power production.
- b. Installation and operation of a high frequency sound and light fish protection system.
- c. Extensive fishery monitoring to determine the impacts of pump storage operation at RBR and the effectiveness of the fish protection system.
- d. Analysis of the data obtained from the monitoring plan to determine if additional fish protection measures and/or fishery mitigation is needed.

The studies conducted during the Richard B. Russell Fish Entrainment Study and reported in this document fulfill all the testing requirements of the T&MP. As specified in that plan, these studies were conducted using procedures approved by an interagency Coordination Group.

Phases I and II of the T&MP

The T&MP essentially involves three phases of testing and monitoring. Phase I provided for monitoring to avoid significant fish kills during initial testing of the pump-turbines in regards to their mechanical and electrical certification. In Phase II, one or more pump-turbines were sampled at regular intervals during the pumpback phase and during more than four-unit conventional generation (2 to 4 days per month) to assess the impacts of fish entrainment and mortality. A report describing the results of Phase II testing, "Richard B. Russell Phase II

Completion Report: Impacts of Two-Unit Operation" was completed and coordinated with the natural resource agencies in February 1995.

Phase III of the T&MP

This report presents detailed results of Phase III testing and monitoring as provided for in the T&MP. Phase III studies were conducted (April 1 to October 31, 1996) under operational scenarios as close to full-scale commercial operation levels as the sampling constraints of recovery netting allowed. Phase III data presented in this report include:

- a.* Pumped storage fish entrainment sampling using full or partial recovery net.
- b.* Summaries of conventional netting results obtained prior to collection of Phase III data.
- c.* Supporting studies such as recovery net calibration and fish mortality testing.
- d.* Results of calibration for fixed-aspect hydroacoustics sampling of fish entrainment.
- e.* Ichthyoplankton entrainment.
- f.* Summaries of baseline data collection.
- g.* Population estimates for threadfin shad and blueback herring.
- h.* Risk assessment of pump storage operation using population modeling.
- i.* Mobile hydroacoustics summaries.
- j.* Commercial and sport harvest
- k.* Predictions of future entrainment.
- l.* Summary water quality impacts on striped bass.

The studies provided for in the RBR Fish Entrainment Studies and the T&MP have been exhaustive and produced a wealth of complex fishery and water quality data. This summary provides only a synopsis of the results. For more detailed information, the reader should examine the main reports.

Phase III-Entrainment Results

Phase III monitoring was conducted in 1996 from April 1 to October 31, because long-term baseline fish sampling indicated the time period of maximum biological activity downstream of RBR Dam occurred during these months. Since Phase III monitoring did not include sampling of pump storage entrainment for the months of November through March, Phase II data were reanalyzed to develop species-specific proportionalities to expand Phase III entrainment data to provide an estimate of annual entrainment. Species-specific entrainment mortality studies were also conducted to determine how many fish could survive passage through the dam. Based on this work, the following conclusions were drawn:

- a. Using the expanded annual entrainment estimates, a total of about 10.1 million fish are projected to be entrained during pumping operations at RBR in a dry year, compared to about 1.2 million fish projected to be entrained during pumping operations in a wet year. In both cases, entrainment is dominated by threadfin shad (92 percent in dry years and 94 percent in wet years).
- b. Entrainment of fish during Phase III pump storage operation is a small percentage of the total numbers of fish in JST Lake (maximum annual estimate of 0.47 percent by number and 0.69 percent by biomass). Projected annual entrainment totals by species are less than 1.0 percent of population estimates for all common species except white perch, for which 1.3 percent of the population is entrained.
- c. Based on data collected during Phase III monitoring and adjusted for the percentage of each species that successfully pass through the dam, pump-back entrainment by number is dominated by threadfin shad (90.9 percent), blueback herring (6.4 percent), and white perch (1.3 percent).

Phase III-Adjustment for Survival

Not all fish die that are entrained. Passage survival studies for entrained fish during pumping operation found mortality ranging from 0.0 to 100.0 percent. The results were dependent upon the species tested and the month in which the test was conducted. As an example, survival of passed fish is substantially greater during cooler water temperatures (April and May). Passage mortality estimates in this study are conservative (high) because fish passage mortality is generally not reduced by mortality resulting from capture, handling, transport, and holding of fishes associated with mortality studies. Based on Phase III work, the following conclusions were made:

- a. Total entrainment mortality during Phase III was 3.66 million fish with a biomass of 13,016 kilograms (1 kg = 2.2 lb); 90 percent of these fish were less than 3.5 in.

- b. Total annual entrainment mortality is predicted to be 8.07 million fish (0.45 percent of total population) for a dry year and 1.13 million fish (0.06 percent of total population) for a wet year with a biomass of 23,434 kg (dry year), and 3,032 kg (wet year). In an average year, annual entrainment mortality is predicted to be 6.10 million fish (0.34 percent of total population) with a biomass of 22,118 kg.

Summary-Composition of Entrained Fish

The percentages that each species of fish will contribute to entrainment will vary by water year. This variation occurs because of the interplay between seasonal patterns of entrainment and relative changes in the proportion of hours of pumping each month. Based on Phase III data, the following determinations were made:

- a. Threadfin shad (90.9 percent by number and 35.5 percent by biomass), blueback herring (6.4 percent by number and 33.7 percent by biomass), white perch (1.3 percent by number and 19.2 percent by biomass), and black crappie (0.7 percent by number and 6.1 percent by biomass) dominated the entrainment samples. These four species constituted 99.3 percent by number and 94.5 percent by biomass of the entrainment samples.
- b. Entrainment percentages for other species important to the sport fishery of JST Lake were largemouth bass (0.03 percent by number and 0.02 percent by biomass), striped bass (0.02 percent by number and 0.78 percent by biomass), and hybrid bass (0.01 percent by number and 0.73 percent by biomass).

Summary-Size Composition of Entrained Fishes

Based on Phase III testing and monitoring, the following conclusions were reached:

- a. 99.85 percent of all fishes entrained were less than 8.5 in. long.
- b. Size composition of entrained fishes reflects the species composition, with 90 percent of netted entrained fishes occurring in the 1.5 to 3.4-in. size class.
- c. The 3.5- to 5.4-in. size class accounted for 4 percent of the total and the 5.5- to 8.4-in. size class account for 6 percent.
- d. Size composition of key sport species also was generally characterized by these smaller size classes. The most commonly entrained sport fish was white perch. Of the white perch estimated to have passed through the

turbines during Phase III, about 36 percent were of harvestable size (greater than or equal to 6.5 inches long) with the intermediate size class (4.5- to 6.4-in. fish) containing 58 percent of the sample. About 6 percent of the sample was in the fingerling (less than 4.4 in. in length) size class.

- e. For black crappie, the intermediate-size class (4.5 to 6.4 in.) fish dominated the sample (84 percent). About 9 percent of the total take of black crappie were in the harvestable size class (greater than 6.5 in. in length).
- f. A total of 595 striped bass were estimate to have been killed passing through the dam (556) or impinged on the bar screen veneer (39) during Phase III sampling. Of that total, 97 percent were less than 15 in. long and only 3 percent were 15 in. or longer.
- g. A total of 279 hybrid bass were estimated to have been killed either passing through the dam (246) or impinged on the bar screen veneer (33) during Phase III sampling. Of this total, 84 percent were less than 15 in. long, and only 16 percent were 15 in. long or longer.

Summary-Conventional Generation Passage

Conventional generation passage was not monitored during Phase III studies. The results of netting surveys conducted prior to Phase III were employed to estimate conventional generation entrainment that could have been expected. The following estimates of the effects of the addition of pumped storage on conventional generation entrainment were derived:

- a. Data indicates that less fish pass during worst-case (dry year) conventional generation than pass during pump storage operation, with most passage occurring during the winter time (total annual estimate not adjusted for survival of 5.9 million fish).
- b. Threadfin shad (87 percent), blueback herring (6.7 percent), and yellow perch (4.2 percent) comprise 98.2 percent of entrainment by hourly rate.
- c. It is highly probable that survival of fishes entrained during generation is greater than during pumping operation.

Summary-Water Quality Impacts, Striped Bass Habitat, in JST Lake

Water temperature, dissolved oxygen (DO) monitoring and multi-dimensional water quality modeling both indicated temperature impacts associated with pump storage operation in the tailwater of RBR Dam. This is important because the

RBR tailwater is considered to be an important striped bass fishery, and temperature and DO are critical parameters in determining suitable striped bass habitat. Water quality data collected from the summer period (July through September, 1992-1996) were examined to characterize tailwater as well as lakewide striped bass habitat dynamics in JST Lake.

Two categories of striped bass habitat were defined by the following bounds: preferred habitat (water having DO greater than 3.0 parts per million and temperature less than 24 degrees C) and restricted habitat (DO greater than 3.0 parts per million and temperature less than 27 degrees C). The following conclusions were reached:

- a. Striped bass restricted habitat in the RBR tailwater did not decrease with RBR operations in 1996 compared to conditions in 1993, a year having similar lake elevation patterns to 1996 but without pumpback operation.
- b. A loss in striped bass preferred habitat in the RBR tailwater was evident in July and August. This was related to an increase in the mean water temperature released from RBR Dam which increased bottom temperatures recorded in the RBR tailwater. In 1996, water temperatures in the tailwater may have exceeded the preferred habitat criteria resulting in an out-migration of striped bass into the main body of the lake (based on an apparent reduction of sport harvest of striped bass, 1996 creel data). The tailwater area comprises less than 2 percent of JST Lake.
- c. Lakewide restricted habitat did not show a noticeable decrease in 1996 compared to 1993. Lakewide preferred habitat was lowest in September, 1996, but was similar to 1993 estimates. Preferred habitat was available in portions of the lake other than the tailwater.

Summary-Water Quality Changes in RBR Lake

Pumped storage operation of RBR Dam resulted in warming of the bottom-layer of water in RBR Lake with no noticeable change in water temperature in the upper-layer of water in RBR Lake. Despite the slight warming of the bottom-layer of water in the RBR forebay, the volume of RBR Lake providing high enough oxygen levels to support fish increased. Pump storage operation resulted in improvements to the dissolved oxygen levels in the bottom-layer of RBR Lake.

Summary-Ichthyoplankton Entrainment

The Phase III arithmetic mean ichthyoplankton entrainment total of 125 million was dominated by clupeids, with estimated totals of 54 million for threadfin shad when ichthyoplankton could be keyed to species and 111 million when identification was limited to the family level. The number of ichthyoplankton that could

reasonably be expected to occur in JST Lake was estimated at 160 billion. Phase III ichthyoplankton total entrainment projected for dry year pumping is 266 million. The number of ichthyoplankton entrained under worst-case pump storage operation is about 0.17 percent of the estimated total ichthyoplankton number that could be reasonably expected to be produced during the spawning season for the entire lake.

Summary-Predictions of Future Entrainment

Expansions to predict entrainment (all adjusted for survival) to future operation are based on the hourly fish passage rate obtained from netting samples for each month multiplied times the unit hours of operation anticipated for wet, average, and dry years. The following predictions were derived:

- a. The anticipated annual entrainment totals, adjusted for survival, for the various water years differ substantially, from 1.1 million for a wet year, 6.1 million for an average year, to 8.1 million for a dry year. For the worst-case (dry year), this means that approximately 0.45 percent by number and 0.28 percent by weight of the fish in JST can reasonably be expected to be killed by turbine passage during a dry year.
- b. About 313,000 blueback herring can reasonably be expected to be killed during a dry year operation. On an annual basis, the blueback herring mortality is 0.46 percent of the total population in JST Lake.
- c. Approximately 7.6 million threadfin shad could be expected to be killed during dry year pumping operation. This represents about 0.58 percent of the population of threadfin shad that were estimated in JST Lake in August of 1996.
- d. Entrainment data for white perch indicates that 98 percent of the mortality for this species occurs during the October through April timeframe. White perch shows the greatest potential for impact of any species investigated with 1.33 percent of the population being killed by pumping operation during April through October.
- e. The total estimated number of black crappie that would be killed is 0.52 percent of the long-term average abundance of black crappie in JST Lake of 6.4 million and 0.23 percent of the over 14 million black crappie that were estimated for JST Lake in 1994.
- f. Approximately 1,484 striped bass or 0.66 percent are estimated to be killed on an annual basis under worst-case pumping conditions. The total population of striped bass in JST is unknown. However, the management goal is 3 striped bass per acre of lake area. Therefore approximately 225,000 catchable striped bass could be reasonably expected to occur in JST Lake.

- g. For an annual cycle of operation under worst-case conditions, a total of 1,016 hybrid bass or 0.19 percent can reasonably be expected to be killed. The total number of hybrid bass in JST Lake, is unknown. The management goal is to have an abundance of 7 hybrid bass per acre of lake area. Consequently, approximately 525,000 catchable hybrid bass could be reasonably expected to occur in JST Lake.

Summary-Population Decline Risk Assessment

Risk based population modeling was used to assess the impacts of pumped storage operation on five species: threadfin shad, blueback herring, striped bass, hybrid bass, and black crappie. Two different scenarios were used to evaluate population decline potential. "Scenario B" simulations were restricted to evaluations of Phase III monthly rates projected to annual average water year entrainment. Scenario B simulations were based on the most complete data sets to simulate commercial operation at RBR. Results of the risk analysis are presented as the maximum risk (probability) that population levels will fall below baseline - simulation results at least once over a period of 50 years. The following predictions were obtained:

- a. Population levels of threadfin shad appear to be unaffected by entrainment losses.
- b. Population levels of blueback herring appear to be minimally affected by projected average year entrainment losses with a maximum increase in the probability of decline of 3 percent. Under extreme entrainment conditions, the risk assessment modeling shows a maximum increased risk of 53 percent above background that the population will drop below 11.3 million fish once over a period of 50 years. This entrainment scenario of the modeled baseline population is 14 times higher than the dry year annual worst-case loss obtained from Phase III data.
- c. Hybrid bass population size under the projected mean annual entrainment total shows a stable population reduction of 10,000 fish and a maximum increased risk of decline of 3 percent. The maximum entrainment scenario of 6 percent increases the risk by 15 percent that the population will decline below 46,000 fish at least once over the next 50 years. The 6 percent entrainment scenario is over 7 times the projected dry year annual worst-case loss of 2,134 fish. Based on the model, the loss of hybrid bass can be completely compensated by increasing the stocking rate to 746,000 fish per year (20 percent increase).
- d. Striped bass Scenario B entrainment produced a maximum increased risk of decline of 4 percent. The maximum entrainment scenario of 8 percent of the baseline modeled population increases the risk by 22 percent that the population will decline below 50,000 fish at least once over a period of 50 years. This scenario is 4 times the projected dry year worst-case loss of

2,789 fish based on annual projections using Phase III data. Based on the model, the loss of striped bass can be completely compensated by increasing the stocking rate to 286,700 fish (28 percent increase).

- e. There was not enough data on the black crappie population in JST Lake to produce a model with any certainty.

Summary

Conclusions

The final phase of passage monitoring and impact assessment to determine the effects of pumped storage operation on fish communities and water quality conditions in both J. Strom Thurmond (JST) Lake and Richard B. Russell (RBR) Lake was completed on 31 October 1996. Analysis of the data generated the following general conclusions. Additional conclusions having fishery implications which were obtained from water quality studies are documented in a separate completion report.

- Long-term, baseline fishery studies and creel surveys of JST Lake, the downstream lake from RBR Dam, indicate the presence of an abundant and diverse fish community supporting a valuable multi-species fishery.
- Entrainment of fish during Phase III (commercial pumping rates) pumped storage operation is a small percentage (maximum annual estimate of 0.47 percent by number and 0.69 percent by biomass) of the total numbers of fish in JST Lake. Projected annual entrainment totals by species are less than 1.0 percent of population estimates for all common species except white perch for which 1.3 percent of the population is entrained.
- Based on data collected from April to October and adjusted for the percentage of each species that successfully pass through the dam, pumpback entrainment by number is dominated by threadfin shad (90.9 percent), blueback herring (6.4 percent), and white perch (1.3 percent), with no other species contributing more than 1.0 percent of the total.
- Total entrainment mortality during Phase III was 3.66 million fish (0.20 percent) with a biomass of 13,016 kilograms (1 kg= 2.2 lb), 90 percent of these fish were less than 3.5 inches. For Phase III months, projected worst case (dry year) entrainment mortality was 4.84 million fish (0.27 percent) with a biomass of 20,010 kg. Total annual entrainment mortality is estimated at 8.07 million fish (0.45 percent) for a dry year and 1.13 million fish (0.06 percent) for a wet year with a biomass of 23,434 kg (dry year) and 3,032 kg (wet year).

- Conventional generation passage estimates that can be attributed to operation of the 4 pumped storage units are based on data collected prior to Phase III. These data indicates that less fish pass during worst-case conventional generation (total annual estimate not adjusted for survival of 5,918,426) than pass during pumped storage operation, with most passage occurring during the winter time. Threadfin shad comprise 87 percent of the annual passage of fish through the RBR Dam during conventional generation.
- Direct testing of the fish protection system and overall reductions in entrainment as the protection system became finalized during the phased testing program indicate the fish protection system is effective and should be an integral part of future operation.
- All monitoring data collected since August 31, 1993 combined with population risk assessment indicate that pumped storage operation at RBR Dam is possible with minimal impact on the fishery of JST Lake. Risk assessment was performed by comparing population model predictions of abundance of threadfin shad, blueback herring, hybrid bass, striped bass, and black crappie with and without entrainment losses. The risk assessments indicate that the probability of local extinction is negligible for the five species evaluated. Mean entrainment rates based on all data combined from August 31, 1993 to October 31, 1996 and mean Phase III annual entrainment data, increases the maximum risk of population decline at any population level by a maximum of 7.0 percent or less for threadfin shad and blueback herring. The mean entrainment rates for all data combined and annual Phase III data for hybrid bass and striped bass also indicate a maximum risk of decline of 7 percent. According to model predictions, increased stocking rates for these two species can completely compensate for even multiples of worst case entrainment. Due to a lack of vital information on black crappie, the authors of the population model recommend that the results of the black crappie model be regarded with skepticism. The risk of decline as described in these models is the risk that the population will decline to a certain level at least once in a 50 year period.
- Pumped storage operation of RBR Dam results in warming of the bottom-layer of water in RBR Lake with no noticeable change in water temperature in the upper-layer of water in RBR Lake. Despite the slight warming of the bottom-layer of water in RBR Lake forebay, cool water habitat for striped bass and hybrid bass, i.e., water with dissolved oxygen concentrations greater than 3.0 parts per million and water temperatures less than 27 °C, will increase with pumped storage operations. This is due to improvements in dissolved oxygen levels in the bottom-layer of water in RBR Lake.
- Temperature and dissolved oxygen patterns in lower JST Lake generally fell within historic ranges during Phase III. There were no discernable changes in JST down lake patterns that could be attributed to pumped

storage operation. In the tailwater of RBR Lake, water temperatures increased to levels that were below 27 °C (a commonly employed upper threshold above which striped bass cease to feed) but high enough (24 °C) to possibly cause cool water fish to redistribute to the main lake area of JST during July and August. Cool water habitat of sufficient dissolved oxygen (greater than 3.0 parts per million) was available within JST Lake to support cool water fishes in all months.

- The temperature of releases from JST Dam were not substantially different in 1996 than in previous years. However, the releases contained higher levels of DO than observed in previous years.
- The volume of RBR Lake providing high enough oxygen levels to support fish has been increased by pumped storage operation suggesting an increase in volume of lake habitat available to fish in the main part of RBR Lake and, therefore, an increase in fish production in RBR Lake.
- Entrainment of fish eggs and larval fish was estimated at 125 million (-0.08 percent) of the 160 billion estimated to have been produced during the spawning season of JST Lake. Larval fish entrainment was dominated by threadfin shad and blueback herring with no fish eggs collected in the samples.
- Substantial numbers of fish of different species can survive passage through the turbines during pumped storage operation when water temperatures are cooler in the winter and spring.
- The fixed-aspect hydroacoustics monitoring system met the performance criteria required in the Testing and Monitoring Plan (TMP).
- Population estimates of threadfin shad and blueback herring indicate springtime populations of 57 million and 68 million respectively. Summer-time total population abundance of 1.322 billion was obtained for threadfin shad. A mark-recapture based population estimate indicated the presence of 84 million adult blueback herring (mean length = 5.5 in. \pm .2 in.).
- The estimate of average annual commercial catch of blueback herring of over 500,000 fish exceeds entrainment losses.
- Mobile hydroacoustics monitoring indicates a high correlation between entrainment of threadfin shad and the population abundance of threadfin shad in the RBR tailwater.
- No adverse impact on fish distribution or entrainment as a result of construction of the conveyance channel was observed.

Background

The U.S. Army Corps of Engineers, Savannah District (CESAS), develops and manages water resources on the Savannah River by constructing and operating reservoir projects. RBR Dam and Lake, begun in 1974, is the most recent of the Savannah River impoundments. RBR dam has four reversible turbines and four conventional turbines. The reversible turbines can be used as pumps during periods of low power demand to replenish upstream storage for peak generation needs.

JST Lake, located immediately downstream of RBR Dam, has an established sport fishery that is monitored and managed (which includes annual stocking) by the states of Georgia and South Carolina. A partial list of species important to the JST Lake fishery includes striped bass, white bass, crappie, several species of sunfish, white catfish, channel catfish, bullhead, hybrid bass, largemouth bass, yellow perch, gizzard shad, blueback herring, threadfin shad, flathead catfish, and, recently, white perch. The States of Georgia and South Carolina, the U.S. Fish and Wildlife Service, and the District all agreed that potential turbine mortality of entrained fishes during pumpback at RBR and the potential impact on the JST fishery should be addressed.

In 1986 the Corps of Engineers (CE) initiated an exhaustive study, the Richard B. Russell Fish Entrainment Study (RBRFES), to provide baseline data on the fish community of JST, predict entrainment and fish mortality, develop fish protection measures, and monitor entrainment through the units as part of a three-phase Testing and Monitoring Plan (TMP) agreed to by the CE and resource agencies. This report presents results and findings of Phase III testing and summarizes all findings since the inception of the TMP as an aid to decision-making regarding pumped storage operation at RBR Dam. Phase I and II entrainment sampling and pumping operation were considerably less than Phase III pumping operation. Phase III studies were conducted under operational scenarios as close to full-scale commercial operation levels as the sampling constraints of recovery netting allowed. Duration and timing of pumped storage operation are affected by limitations imposed by deployment and retrieval of the recovery nets. Results from the phased testing program are employed to determine if commercial pumped storage operation at Richard B. Russell Dam is possible without jeopardizing the fisheries of either RRB or JST Lakes.

The most important Phase III sampling activities include estimating fish entrainment under commercial levels of operation using partial and full recovery nets. All data collection activities described in this report meet the sampling requirements described in the TMP or were adjustments to the requirements of the TMP suggested by and agreed to by the Technical Coordination Group (CG). In addition to recovery netting, Phase III activities included estimating fish mortality rate resulting from turbine passage during pumping operation, supporting studies such as recovery net calibration, validation of fixed-aspect hydroacoustics to recovery net sampling, ichthyoplankton entrainment monitoring, summaries of baseline data collection, risk assessment of pumped storage operation using

population modeling, population estimation for threadfin shad and blueback herring, mobile hydroacoustics surveys, summary of water quality impacts on striped bass, and comparisons of projected entrainment totals to the total numbers of ichthyoplankton, juvenile, and adult fishes estimated to be in JST.

Phase III Baseline Data Collection

Baseline data are used to assist in determining if pumpback operation affects the composition of the fish community or the spatial or temporal distribution of fishes. Baseline sampling for the RBRFES was initiated on JST in 1986 and has been dynamic over the eleven-year study period. The sampling gears used, the locations of sampling, and the frequency of sampling changed over time in response to the changing informational needs and objectives of the RBRFES. Baseline sampling occurred throughout JST reservoir from 1986 to 1990 to evaluate reservoir wide trends. From 1990 to 1996, sampling was limited to the upper end of the reservoir to monitor near-field trends below RBR dam. Also in 1990, sampling was initiated on the lower third of RBR Lake to monitor near-field trends upstream of RBR dam.

The general objectives of baseline monitoring activities were to determine:

- What are the principal components of the fish communities in the two reservoirs?
- How do the communities vary spatially within reservoirs in terms of species composition and biomass?
- How do the communities vary seasonally and annually in terms of species composition and biomass?
- Is the tailwater area immediately below Russell dam unique?

Baseline monitoring activities included gillnetting, electrofishing, cove rotenone sampling, larval fish and zooplankton sampling, purse seining and draft tube sampling. General information obtained from each sampling gear is briefly described below. Gillnetting, electrofishing and rotenone sampling were used to describe the fish communities and to assess spatial and temporal trends in abundance of fishes; larval fish sampling was used to describe spatial and temporal patterns of fish reproduction; zooplankton sampling was used to describe spatial and temporal trends in abundance of zooplankton; purse seining was used to describe size distributions of fish and verify target strengths for hydroacoustics sampling; and, lastly, draft tube sampling was used to determine the species, numbers, and sizes of fish that are attracted to the draft tubes thus being potentially susceptible to immediate entrainment during pumpback.

Phase III Netting Description

Phase III entrainment monitoring was conducted from 1 April to 31 October, 1996. This time period was selected for sampling because long-term baseline fish sampling using a variety of gears indicated the time period of maximum biological activity downstream of Richard B. Russell Dam occurred during these months. The number of hours per month of recovery net sampling contrasted to the number of hours per month of Phase III pumpback operation is shown in Table S-1 as are the number of hours of operation projected for wet, average, and dry years. Note that the number of hours of sampling was generally constant varying from 66.3 hours in April to 84.4 hours in August. In general, recovery net samples were collected 16 times per month during Phase III with each of the four pump turbines being sampled four times per month.

A total of 3129 unit hours of pumping operation occurred at RBR Dam between the months of April to October. This total approximates an anticipated average water year of pumping operation of 3830 unit hours during these same months. Phase III operation was substantially greater (factor of 4) than anticipated wet year pumping operation of 803 unit hours and about 33 percent less than dry year condition pumping operation of 4633 unit hours for the same months. The Phase III data set should be a good predictor of fish entrainment to be expected under average water year conditions (Table S-1).

Phase III Pumpback Netting Results

During Phase III, a total of 577,686 fish (0.03 percent of total population) with a biomass of 3442 kilograms (0.04 percent of total biomass) were collected by full recovery netting (net covers all or most of exit jet) or partial recovery netting (net covers one of two bays of intake flow) during pumped storage operation. This estimate is corrected for net efficiency and for coverage for partial recovery netting. The number of recovered fish was expanded to estimate total power plant passage during pumping operation by calculating an arithmetic mean monthly passage rate (fish/hour) separately for each of the four pump units. An overall species specific entrainment rate for the power house was obtained as the mean of the entrainment rate of each unit. Basing the overall entrainment rate on the mean of the mean entrainment rate for each unit prevented the overall entrainment rate from being biased by units that were sampled proportionally more than other units. A monthly estimate of entrainment was obtained by expanding the calculated rate by the total number of unit hours of operation for that month. During Phase III, a minimum of sixteen net samples were collected per month with each sampling duration lasting a minimum of four hours. A total of 3,853,317 fish (0.21 percent of total population) greater than or equal to 1.5-in. long having a biomass of 17,673 kg (0.21 percent of total biomass) were estimated to have been entrained through the pump units during Phase III pumpback operation (Table S-2). An additional 85 fish having a biomass of 56 kg were estimated to have been impinged on the bar screen veneers that physically exclude fish greater than about

12 in. long from entering the draft tube openings during pumping operation (Table S-3). Total impingement of fish on the bar rack veneers during Phase III sampling was estimated at 326 fish with a biomass of 172 kg. Impingement of fishes on the screens is a very minor component of impact on the fish community of J Strom Thurmond Lake resulting from pumped storage operation of Richard B. Russell Dam (Table S-3).

Phase III monitoring did not include sampling of pumped storage entrainment in the months of November, December, January, February, or March. Phase II data, collected from August 1993 to August of 1994, were reanalyzed to develop species-specific proportionalities, defined as (annual entrainment)/(April-October entrainment), that were used to expand Phase III entrainment data to provide an estimate of annual entrainment that could be reasonably expected to occur during unsampled months to generate an annual estimate of turbine loss for each commonly entrained species. This proportionality should be considered an approximate guide only because the relative abundances of fish can change substantially, particularly species that reproduce in large numbers like threadfin shad. Table S-5 presents the results of this expansion for entrainment without adjusting for turbine passage survival. Using the expanded annual entrainment estimates, a total of about 10.1 million fish (0.56 percent of total population) are projected to be entrained during a dry year pumping operation compared to about 1.2 million fish (0.07 percent of total population) projected to be entrained during a wet year pumping operation. In both cases, entrainment is dominated by threadfin shad (92 percent in dry years and 94 percent in wet years). Note that threadfin shad is the only commonly entrained fish for which winter time entrainment totals approached April-October entrainment totals for dry year conditions (48% of threadfin shad entrainment would occur during Phase III months).

Adjustments for Survival for Pumpback

Passage survival studies for entrained fish during pumping operation found mortality ranging from 0.0 to 100.0 percent. The results were dependent upon the species tested and the month in which the test was conducted. The addition of survival information changed the numbers of fish impacted by pumping by only 4.9 percent because the numbers are dominated by threadfin shad passed during the late summer and early fall when estimated turbine passage mortality of threadfin shad approached 100.0 percent. However, addition of survival information changed the biomass of fish impacted by pumping by 26 percent because passage of larger fish was greater during the spring months when estimated turbine passage mortality was reduced. The survival adjustment for annual estimates of turbine passage produces a proportionally greater reduction in fish loss than the survival adjustment for Phase III months. Survival of passed fish is substantially greater during cold water temperatures (November through March) that were not part of Phase III (compare Table S-5 with Table S-7). Turbine passage mortality estimates are conservative because fish passage mortality is generally not reduced by mortality resulting from capture, handling, transport, and holding of fishes (all components of control mortality) associated with conducting mortality studies.

These stresses are known to result in mortality of some recovered fish, but were not incorporated into turbine passage mortality estimates. Considerable effort was made to estimate control mortality with limited success for abundant species such as blueback herring and threadfin shad, particularly in the summertime. Some success for hardy species such as bluegill and catfish was achieved. The total entrainment mortality during Phase III was 3.66 million fish (0.20 percent of total population) having a biomass of 13,016 kg (0.15 percent of total biomass) (Table S-6).

Species Composition of Entrained Fish

The following general trends in fish entrainment data are based on net data (net sample expanded for efficiency and coverage) adjusted by survival information (Table S-6). Note, however, that percentages that each species will contribute to total entrainment will vary by water year. This variation occurs because of the interplay between seasonal patterns of entrainment and relative changes in the proportion of hours of pumping for each month. The proportion that each month of pumpback capacity contributes to total annual pumpback capacity will change with water year (Table S-1).

Based on Phase III data, threadfin shad (90.9 percent by number and 35.5 percent by biomass), blueback herring (6.4 percent by number and 33.7 percent by biomass), white perch (1.3 percent by number and 19.2 percent by biomass), and black crappie (0.7 percent by number and 6.1 percent by biomass) dominated the entrainment samples (Table S-6). These four species constituted 99.3 percent by number and 94.5 percent by biomass of the entrainment samples. Entrainment percentages for other species important to the sport fishery of JST Lake were largemouth bass (0.03 percent by number and 0.02 percent by biomass), striped bass (0.02 by number and 0.78 percent by biomass), and hybrid bass (0.01 percent by number and 0.73 percent by biomass). An additional 39 striped bass and 33 hybrid bass were impinged on the bar screen veneers used to physically exclude large fish from the turbines.

Size Composition of Pumpback Entrained Fishes

For purposes of comparability, fish size categories used to describe predicted entrainment in the Final Supplement to the Environmental Impact Statement are used to describe Phase III fish entrainment in this report. Size composition of entrained fishes reflected species composition with 90 percent of netted entrained fishes occurring in the 1.5- to 3.4-in. size class (Table S-8), the same percentage as the percent composition of threadfin shad (Table S-6). Nearly 100 percent of all fishes entrained were less than 8.5 in. long (Table S-8). The abundance of the next two size classes appears to be inverted with the 3.5- to 5.4-in. size class at 4 percent of the total and the 5.5- to 8.4-in. size class at 6 percent of the total (Table S-8). The apparent inversion in abundance of the next two size classes

reflects both the increased number of inch classes in the 5.5- to 8.4 in. size category and the species composition of entrained fish. Blueback herring, the second most abundant species in the entrainment sample occur mostly in the 5.5- to 8.4 in. size class. Substantially less than one percent (0.15 percent) of the entrainment sample was in the greater than 8.5 in. size class.

Size composition of key sport species entrained during Phase III sampling also was generally characterized by the smaller size classes (Table S-8). The most commonly entrained sport fish was white perch (Table S-6). Of the 26,459 white perch estimated to have been killed passing through the turbines during Phase III, about 36 percent were of harvestable size (greater than or equal to 6.5 in. long) with the intermediate size class (4.5- to 6.4-in. fish) containing 58 percent of the sample. About 6 percent of the sample was in the fingerling (less than 4.4 in. in length) size class. Similarly, total black crappie numbers killed by passage through the pump turbines was estimated at 20,104 with intermediate-size (4.5 to 6.4 in.) fish dominating the sample (84 percent of the total). About 9 percent of the total take of black crappie was in the harvestable size class (greater than 6.5 in. in length).

Striped bass and hybrid bass entrainment was identified as a key issue early in project planning. Both state resource agencies stock hybrid bass and striped bass and both species are considered to be valuable sport fishes important to the economies of the local area. Four size classes were used to characterize striped bass and hybrid bass entrainment (Table S-8) so that entrainment of large fish (greater than 14 in. long), of special interest to anglers and resource agencies, could be described. A total of 595 striped bass were estimated to have been killed passing through the dam (556) or impinged on the bar screen veneer (39) during Phase III sampling (Tables S-6 and S-4). Of the total, 97 percent were less than 15 in. long and only 3 percent were 15 in. long or longer (Table S-8). Similarly, 84 percent of the total 279 hybrid bass estimated to either have been killed either passing through the dam (246) or impinged on the bar screen veneer (33) during Phase III sampling (Tables S-6 and S-4) were less than 15 in. long and only 16 percent were 15 in. long or longer (Table S-1).

Conventional Generation Passage

Conventional generation passage was not monitored during Phase III studies. In lieu of conventional generation monitoring during Phase III, the results of netting surveys conducted prior to Phase III were employed to estimate conventional generation entrainment and are presented here to depict entrainment rates that would have been reasonable both during Phase III conventional generation monitoring and also during months not included in Phase III sampling. Note that Phase III passage totals are generally low, with worst case passage estimated at 626,225, and are not of the same magnitude as Phase III pumpback passage (Table S-9). However, passage totals during non-Phase III months of November, December, January, February, and March are substantially higher than during the Phase III sampling, increasing the estimate of fish passing through the dam for a

full annual cycle to 5,918,426 (Table S-10). Considerable passage of fishes during the winter is common at hydropower dams, particularly for threadfin shad. Mortality of threadfin shad is common as the summer boom of threadfin shad is substantially reduced during winter die off. The conventional generation data should be used with caution because in many cases the netting summaries represent passage when only a single unit was running in conventional generation mode. Mean annual entrainment rates (fish/hour) by species for conventional generation netting are presented in Table S-11 to provide an estimate of species composition. Entrainment is dominated by threadfin shad (87.3 percent), blueback herring (6.7 percent), and yellow perch (4.2 percent). These three species together comprise 98.2 percent of entrainment by hourly rate. No direct population estimates are available for threadfin shad and blueback herring in RBR Lake as were performed for JST Lake. However, cove rotenone data were available to allow a comparison of the abundance ranking of threadfin shad and yellow perch in the two reservoirs. From the cove rotenone data, threadfin shad are the most abundant fish in RBR Lake. Entrainment of sport fishes during conventional generation is relatively low for both the Phase III months and non-Phase III months compared to pumpback entrainment. For example, only 72 striped bass, 304 hybrid bass, and 14,075 black crappie are projected to be entrained by worst-case conventional generation compared to 2,789 striped bass, 2,134 hybrid bass, and 69,465 black crappie during worst-case pumpback operation (numbers not adjusted for passage survival). These comparisons are not adjusted for survival, although it is highly probable that survival during conventional generation is greater than during pumping operation.

Striped Bass Temperature Habitat

Water temperature and dissolved oxygen (DO) monitoring and multi-dimensional water quality modeling both indicated temperature impacts associated with pumped storage operation in the tailwater area of RBR Dam. These impacts coincided with an apparent decline in striped bass and hybrid bass harvest in 1996. Water quality data collected from the critical summer period (July-September, 1992-1996) were examined to characterize tailwater and lakewide striped bass habitat dynamics in JST Lake. Water quality dynamics relative to striped bass requirements are presented because they are better known and more restrictive than hybrid bass water quality requirements.

Two categories of striped bass habitat were defined by the following bounds: preferred habitat (water having DO greater than 3.0 parts per million and temperature less than 24 °C) and restricted habitat (DO greater than 3.0 parts per million and water temperature less than 27 °C). Striped bass restricted habitat in the RBR tailwater did not decrease with RBR operations in 1996 compared to conditions in 1993, a year having similar lake elevation patterns to 1996. However, a loss in striped bass preferred habitat was evident in the RBR tailwaters. The loss in preferred habitat was related to an increase in the mean water temperature released from RBR Dam and increased bottom temperatures recorded in the RBR tailwaters. The warming of the tailwater of RBR Dam may have contributed to

the apparent reduction of sport harvest of striped bass and hybrid bass in the RBR Dam tailwater.

Lakewide restricted habitat did not show a noticeable decrease in 1996 compared to 1993. Lakewide preferred habitat was lowest during September, 1996, but was similar to 1993 estimates. Preferred habitat was available in other portions of the lake other than the tailwater. In 1996 water temperatures in the tailwater may have exceeded the preferred habitat criteria resulting in an out-migration of striped bass and other cool water species into the main body of the lake. Lakewide habitat volumes estimated from the CE-QUAL-W2 water quality model indicated less habitat in years when lake levels are lower.

Ichthyoplankton

Ichthyoplankton entrainment during pumpback operation was monitored during Phase III and crude temporal and spatial distributions of ichthyoplankton in the tailwater of RBR were described using mobile sampling. During Phase III, ichthyoplankton entrainment was monitored by consolidating gravity flow from 3/4-in. diameter pipes previously installed to service pressure meters, unlike in previous years when ichthyoplankton entrainment was monitored with plankton nets fished in the discharge jet during pumping operation (Table S-12). Mobile surveys in the tailwater indicated that ichthyoplankton density varied from about 1 per 100m³ near the dam to about 50 per 100m³ in Russell Creek, a small tributary near RBR Dam. Phase III arithmetic mean ichthyoplankton entrainment total of 125 million (0.08 percent of total population) was dominated by clupeids with estimated totals of 54 million for threadfin shad when ichthyoplankton could be keyed to species and 111 million when identification was limited to the family level. Projected ichthyoplankton total entrainment for dry year pumping is 266 million (0.17 percent of total population). Lakewide ichthyoplankton surveys were not conducted during Phase III. The number of ichthyoplankton that could reasonably be expected to occur in JST Lake was estimated at 160 billion. This estimate is obtained by expanding area-specific arithmetic mean density estimates for different parts of JST from data collected in 1987, 1988, and 1989. The number of ichthyoplankton entrained under worst-case pumped storage operation is about 0.17 percent of the estimated total ichthyoplankton number that could be reasonably expected to be produced during the spawning season for the entire lake.

Predictions of Future Entrainment

Expansions to predict entrainment (all adjusted for survival) to future operation are based on the hourly fish passage rate obtained from netting samples for each month multiplied times the unit hours of operation anticipated for wet, average, and dry water years. Assessment of entrainment is made at a lakewide scale because the results of both mark-recapture studies for blueback herring and radio telemetry studies on striped bass and hybrid bass indicate that fish are widely

distributed within the reservoir on an annual basis and are not restricted to one portion of the lake. Localized or seasonal effects on fish distributions are presented in the section on temperature habitat for striped bass. Tables S-2 and S-5 (not adjusted for survival) and Tables S-6 and S-7 (adjusted for survival) include columns in which both the numbers and biomasses of netted fish are expanded to predict entrainment under different water years. The anticipated entrainment totals, adjusted for survival, for the various water years differ substantially, from 1,040,553 (0.06 percent) for a wet year to 4,842,477 (0.27 percent) under dry year conditions during April through October. For the entire year (adjusted for survival), entrainment is estimated at 1,125,431 (0.06 percent) for a wet year and 8,067,489 (0.45 percent) for a dry year. For April through October, the average year predicted entrainment mortality of 4,294,869 (0.23 percent) is close to the dry year prediction of 4,842,477 (0.27 percent) because the biggest difference between average and dry year conditions is in the amount of spring-time pumping when the entrainment of fish by number is substantially less than in late summer. However, the April-October difference by biomass between dry water year entrainment (20010 kg) and average water year entrainment (16002 kg) is greater because larger fish are entrained during spring and early summer pumpback operation.

Entrainment samples provide estimates of the numbers of fish passing through the pump-turbines. Species likely to be impacted by turbine passage were evaluated using population modeling based risk assessment. Impacts that are proportionally small are difficult to assess with population modeling because the impact is small relative to the uncertainty in population vital statistics. Therefore, entrainment numbers are also compared to population estimates and to commercial harvest, sport harvest (Table S-3), and other sources of mortality to allow entrainment totals to be placed in a relative context. For example, projected entrainment of 4,842,477 fishes weighing 20,010 kg are projected to be killed under worst case operations (dry water year) for April through October. This is 0.27 percent by number and 0.24 percent by biomass of the total of approximately 1.807 billion fish in JST (Table S-14) with a biomass of 8.4 million kilograms estimated to occur in JST during the late summer (by convention, the time period when many reservoir fishery assessments are made) of 1996. For the entire year, approximately 0.45 percent (8,067,489) by number and 0.28 percent (23,434 kg) by weight of the fish in JST Lake can be reasonably expected to be killed by turbine passage during a dry year.

Population estimates (using two different methods) and commercial harvest data are available for blueback herring against which entrainment totals can be compared. Mobile hydroacoustics provides a total spring-time population estimate of 68 million blueback herring. A total of 294,110 (0.43 percent) blueback herring of all sizes are projected to be killed during maximum pumpback operation (projected dry year operations) during April through October. About 313,069 (0.46 percent) can be reasonably expected to be killed during an entire 12 month cycle. Percentages are based on an estimated total of 68 million blueback herring in JST. Commercial harvest for 6 months of 1994 is 542,854 fish and for the full year in 1995 is 555,377 fish. Harvest in 1995 was considerably reduced because

of an abundance of small fish that are not useable as bait by fishermen. It appears that commercial harvest loss of blueback herring considerably exceeds projected worst-case entrainment losses using Phase III entrainment data. The marked-recapture study to estimate the number of adult blueback herring in the lake sacrificed 144,227 adult fish which is 49 percent of the estimated April-October mortality resulting from worst case pumpback operation.

Population estimates using mobile hydroacoustics are available for threadfin shad greater than 1.2 inches in both March and August of 1996. The March population estimate is 56,577, 931 fish, and the August estimate is 1,322,185,433 fish. The estimated turbine mortality loss of threadfin shad under maximum pumpback operation during Phase III months is 4,426,610 or 0.33 percent of the total or for an annual cycle 7,616,835 individuals representing 0.58 percent of the total numbers using the August population estimate. Threadfin shad have great reproductive potential and typically exhibit "boom and bust" cycles particularly when reduced winter water temperatures result in winter kill of this species. The August estimate is used because entrainment of threadfin shad is highest in August and September during their period of maximum abundance.

No direct population estimates are available for black crappie, white perch, striped bass, or hybrid bass. However, creel surveys are available against which entrainment of harvestable sizes of these species can be contrasted. In addition, routine gillnet surveys have been conducted for 11 years as part of baseline studies in JST Lake and offer a gauge against which to measure pumpback entrainment at Richard B. Russell Dam. Stocking goals are also known for striped bass and hybrid bass and can be used as a crude population estimate against which entrainment can be compared.

Under worst case conditions (dry year pumping operation), 55,197 total and 19,724 harvestable white perch are estimated to be killed by pumped storage operation during the biologically active (Phase III) time period by entrainment (54,939) or impingement (258). This compares to an estimated total of 4,184,270 white perch obtained from cove rotenone expansions for 1994, the first year in which white perch become a significant proportion of the JST fish community. White perch show the greatest potential for impact of any species investigated with 1.33 percent of the population being killed by pumping operation from April through October. Separate annual estimates of entrainment mortality for white perch are not presented because 98 percent of the entrainment of this species occurs during the April through October time frame (Table S-7). Although lake-wide numbers provide no evidence of impact, sport harvest of white perch for 1996 was estimated at 67,816 which is over three times the entrainment totals of harvestable-size fish (19,466) projected during worst-case operation (Table S-8). White perch are the fish population most likely to be impacted by pumped storage operation on the basis of percent of population entrained. As an additional consideration, it is likely that the population estimate used in the analysis (1994 cove rotenone areal expansions) substantially underestimate the abundance of this species. The sport catch for this species was 3,900 in 1994 compared to 67,816 for 1996, suggesting more than an order of magnitude increase in the number of

harvestable white perch in the three-year period. Also, baseline monitoring using gillnets shows that the catch rate for this species has increased at all JST stations from 1992 to 1996.

Black crappie mortality under worst-case pumping scenarios during Phase III months is estimated to be 33,154 fish with 2963 fish being of harvestable size. Long-term sport harvest of black crappie from 1983 to 1996 averages 255,335 fish/year with 203,032 black crappie caught in 1996. Entrainment mortality of harvestable-sized fish is only 1.16 percent of the long term average sport catch and 1.46 percent of the estimated sport catch in 1996 (Table S-13). The total number of black crappie killed is 0.52 percent of the long-term average abundance of black crappie in JST Lake of 6,428,593 and 0.23 percent of the over 14 million black crappie that were estimated for JST Lake in 1994, the most recent year in which cove rotenone data are available. Separate annual estimates for black crappie are not presented because 99 percent of the entrainment mortality loss of this one species occurred during the April through October time frame (Table S-7).

Striped bass mortality under April-October worst case pumping scenarios are estimated to be 1124 fish (1056 entrained and 68 impinged) with 557 being of harvestable size (9 to 14 in. long) and 37 being of desirable size (15 in. long or longer). For an annual cycle, 1484 striped bass can be reasonably expected to be killed by turbine mortality (1394 by entrainment mortality and 90 by impingement mortality) with similar relative size composition presented for the April through October time frame. Annual impingement obtained by expanding Phase III impingement by the Phase II annual expansion factor. The total population size of striped bass in JST Lake is unknown, although the management goal is to have an abundance of 3 striped bass per acre of lake area. Using this as a general guide approximately 225,000 catchable striped bass could be reasonably expected to occur in JST Lake. The worst case April through October entrainment mortality total of 594 (entrainment and impingement) for the two largest size-groups of striped bass is 2.6 percent of the management target. The long term average sport harvest of striped bass is 18,504 fish/year (Table S-11). April through October entrainment mortality of the largest two size classes of striped bass (594) is 3.2 percent ($594 / 225000$) of harvest and entrainment mortality of the largest size group of striped bass (probably most representative of sport harvest) compared to the sport harvest is 0.02 percent ($37/225000$). Routine and moratorium gillnetting (an accepted fishery assessment tool) has been conducted in JST Lake from 1986 to the present to provide relative estimates of spatial and temporal patterns of distribution of large, active fishes such as striped bass and hybrid bass. Average catch of striped bass in gill nets is 187 fish/ year with 59 percent in the desirable length category (15 in. long and longer) or 110 fish/year compared to 37 fish/year of the 15-in. and larger length group entrained by the dam. Effects of the baseline netting program has substantially greater impact on numbers of the largest length group of striped bass than does pumped storage operation under worst-case (dry year) operations.

Hybrid bass mortality under worst case pumping scenario from April to October are estimated to be 616 fish (536 by passage mortality and 80 by impingement) with 329 being of harvestable size (9-14 in. long) and 111 being of desirable size (15 in. long or longer). For an annual cycle of operation, a total of 1016 hybrid bass (884 by passage mortality and 132 by impingement) can be reasonably expected to be killed by pumped-storage operation. The total population size of hybrid bass in JST Lake is unknown, although the management goal is to have an abundance of 7 hybrid bass per acre of lake area. Using this as a general guide, approximately 525,000 catchable hybrid bass could be reasonably expected to occur in JST Lake. The worst case April through October entrainment mortality total of 440 (360 by passage mortality and 80 by impingement) for the two largest size-groups of hybrid bass is 0.08 percent of the management target density. The long term average sport harvest of hybrid bass is 60,304 fish/year. April through October entrainment and impingement mortality of the largest two size classes of hybrid bass is 1.19 percent of harvest and entrainment mortality of the largest size group of hybrid bass (probably most representative of sport harvest) compared to the sport harvest is 0.30 percent (Table S-13). Routine and moratorium gillnetting has been conducted in JST Lake from 1986 to the present. Average catch of hybrid bass in gill nets is 617 fish/year with 69.0 percent in the desirable length category (15 inches long and longer) or 426 fish/year compared to 111 fish/year of the same length group entrained or impinged by the dam. Remarkably, like for striped bass, the effects of the baseline netting program has substantially greater impact on the numbers of larger hybrid bass than does pumped storage operation under worst case conditions. All other species are based on a combination of both states creel estimates.

Population Decline Risk Assessment

In addition to these comparative assessments, risk based population modeling was also used to assess the impacts of pumped-storage operation on five species: threadfin shad, blueback herring, striped bass, hybrid bass, and black crappie. Threadfin shad and blueback herring are both short-lived and their growth is strongly regulated by density (i.e., expansion in numbers at high population levels is inhibited). Striped bass and hybrid bass are long-lived species whose abundance is maintained by stocking. Compared to the other four species, relatively little is known about the vital statistics of black crappie, a naturally reproducing sport fish within JST Lake.

Assessments were performed at two levels: Scenario A is based on entrainment data collected from August 31, 1993 to October 31, 1996 (includes high entrainment events observed between Phases II and III). Scenario A simulations include effects of average water year entrainment rates on each species population as well as the effects of more extreme entrainment rates to determine the sensitivity of the models. Entrainment for extreme events was obtained by adding 3 standard errors to mean entrainment rates for each month and expanding by the number of hours of pumping for each month. Scenario B simulations were restricted to evaluations of Phase III monthly rates projected to annual average water year entrainment.

Scenario B simulations are based on the most complete data sets to simulate commercial operation at RBR because: (1) entrainment rates and population vital statistics are available; (2) all fish protection system and channel modifications were completed and all systems remained constant during the testing period; (3) Phase III samples are the only entrainment data collected under conventional generation and water quality conditions that could be expected under commercial pumpback operation.

Results of the risk analysis are presented as the maximum risk (probability) that population levels will fall below baseline simulation results at least once over a simulation period of 50 years. Results of the risk assessments indicates that entrainment affects the five species to varying degrees.

Threadfin Shad: Population levels of threadfin shad appear to be unaffected by entrainment losses under Scenario B. Under Scenario A the worst case entrainment loss (mean rates plus 3 standard errors) performed as a sensitivity test indicates that the maximum risk of decline increases only 5 percent at a population level of 6 million adults. Even the worst-case entrainment conditions indicate a minimal impact on population levels the risk that the population will decline to any threshold is barely discernible from background.

Blueback herring: Population levels of blueback herring appear to be minimally affected by projected average year entrainment losses under either scenario with a maximum increase in the probability of decline of 7 percent and 3 percent, respectively, above background for Scenarios A and B. Under extreme entrainment conditions (mean entrainment plus 3 standard errors or 12 percent), the risk assessment modeling shows a maximum increased risk of 53 percent above background that the population will dip below 11.3 million fish at least once over a period of 50 years. The 12 percent entrainment scenario of the modeled baseline population ($0.12 \times 51.3 \text{ M} = 6.15 \text{ M}$) is 14 times higher than the dry year annual worst-case loss obtained from Phase III data.

Hybrid Bass: Population size under the projected mean annual entrainment total for Scenario A or B shows a stable population reduction of 10,000 fish and a maximum increased risk of decline of 3 percent. The maximum entrainment scenario of 6 percent increases the risk by 15 percent that the population will decline below 46,000 fish at least once over a period of 50 years. The 6 percent entrainment scenario of the modeled baseline population ($0.06 \times 270,000 = 16,200$) is over 7 times the projected dry year annual worst-case loss of 2,134 fish. Based on the model, the loss of hybrid bass can be completely compensated by increasing the stocking rate to 746,000 fish per year (20 percent increase).

Striped Bass: Population size under projected mean annual entrainment total for Scenario A shows a reduction of 10,000 to 20,000 fish and a maximum increased risk of decline of 7 percent. Scenario B entrainment produced a maximum increased risk of decline of 4 percent. The maximum entrainment scenario of 8 percent of the baseline modeled population increases the risk by 22 percent that the population will decline below 50,000 fish at least once over a period of

50 years. The 8 percent entrainment scenario is more than 4 times the projected dry year worst case loss of 2,789 fish based on annual projections using Phase III data. Based on the model, the loss of striped bass can be completely compensated by increasing the stocking rate to 286,700 fish (28 percent increase).

Black Crappie: The black crappie modeled baseline population stabilized at a mean abundance of 350,000 fish. The average annual harvest of black crappie from 1983 to 1996 was 255,335 fish. The abundance of black crappie in 1994 was over 6 million based on the cove rotenone data. It is therefore unlikely that the model predicted baseline population is correct. The authors of the population model note that there is not sufficient data on the black crappie population in JST to produce a model with any certainty, and skepticism when reviewing the results is recommended.

Hydroacoustics Studies

Hydroacoustics was used to monitor fish entrainment on all intake bays during pumpback operations at the RBR Dam during the Phase III study period. Study objectives for hydroacoustics sampling during Phase III were: (1) determine whether hydroacoustics could be used to predict entrainment rates; (2) measure entrainment through time, among intakes, and depths sampled; and (3) determine whether the entrainment rate changed with the number of units operating. Hydroacoustics sampled 5 times more unit hours of pump operation than the nets during the study period, and provided information about fish entrainment unavailable with net sampling.

Results relating net entrainment rates to hydroacoustics entrainment rates reveal that hydroacoustics can be used to predict monthly entrainment rates. The predictive equations developed were based on both PrePhase III and Phase III data because the differences in entrainment rates, species of fish entrained, fish sizes, and fish depths over the two study periods differed, and either study period alone would not adequately predict entrainment.

Entrainment varied during the Phase III study period. The highest entrainment events predicted with hydroacoustics occurred in July, August and early September when threadfin shad numerically dominated the net catches. During this same period, the fish counted with hydroacoustics tended to be more surface oriented than other months, and the mean fish size entrained dropped from 6.5 in. to 4 in..

Single and multi-unit pump comparisons were made to determine if the number of fish entrained per unit would increase or decrease as more units were brought on line. Results from these comparisons showed that hourly entrainment rates for a single unit pump was half of the entrainment rate by unit for a multi-unit pump event. However, the entrainment rate per unit for a two, three or four unit pump event was not significantly different.

Entrainment rates were also compared between pump events that were preceded by conventional generation within a 24-hour period (pre-generation pumps), and pump events that were not directly preceded by conventional generation (non pre-generation pumps). Entrainment rates for all pumpback units were higher during non pregeneration than pre-generation unit pump events except during the month of June. Although non pre-generational unit events comprised only 13 percent of the total unit pump events during the period of highest entrainment (July-August 1996) for Phase III, 78 percent of the events with entrainment rates >10,000 fish per hour were non pre-generation pumps.

History of Phase Entry and Entrainment Patterns

Initial implementation of the Testing and Monitoring Plan (TMP) identified major challenge areas that had to be resolved before the steps required in the TMP could be completed. These challenges consisted of the following: (1) sampling of the pumpback jet with full recovery nets or fixed aspect hydroacoustics was more difficult than anticipated; (2) the behavior of blueback herring relative to pumpback operation was not well known resulting in high entrainment levels; (3) the entrainment of striped bass and hybrid bass was initially substantially higher than expected. Savannah District committed to the phased study approach in which entry into a succeeding phase of the TMP would not be attempted until the monitoring system was optimized, entrainment was minimized to the lowest level practicable, and challenge areas identified in preceding phases were addressed or resolved prior to entry into succeeding phases. Phase III net sampling to characterize entrainment during pumpback operation consisted of 115 samples over 517 hours of pumping operation. During Phase III, all components of the fish protection system were deployed, all units were operated and sampled, and the full suite of water quality changes associated with commercial operation of the pump units were in effect. In contrast, Phase II (August 1993 to August 1994) sampling was restricted to 50 samples over 296 hours of operation with most sampling (46 of the 50 samples) occurring at unit 5. PrePhase III (September 1994 to March 1996) sampling included 121 samples over 254 hours of operation. Many of the PrePhase III samples were of relatively short duration and the sample was collected primarily to obtain a hydroacoustic/net correlation. Operation was often restricted to the netted unit. During Phase II and PrePhase III operation was insufficient to establish the water quality patterns associated with commercial operation. Phase III data represent the most comprehensive data set available that were collected under the conditions that could be expected with commercial operation.

The high entrainment of blueback herring was minimized three ways. First, daytime pumpback operation was limited because blueback herring were found to concentrate in the deepest water available during the daytime which in the RBR tailrace is immediately in front of the turbines. This behavior may have resulted in the high entrainment in daytime tests. On 30-31 March 1993 a total of 113,000 fish in 8.5 hours passed through Unit 5. On 1 May 93, a total of 77,000 fish passed in 1.5 hours through Unit 5. In 3 daytime samples in July

1992, an estimated 50,994 fish were entrained through Unit 6 in 5.9 hours, although most of the entrainment occurred in approximately 15 minutes. The problem may have been exacerbated by substantial leakage of water (estimated at approximately 200 cubic feet per second) through the wicket gates of the pumped storage units before wicket gate seals were repaired. This leakage may have produced a density flow of cool, well oxygenated water that would attract blueback herring to the draft tube openings, particularly during the day in the summer time. Wicket gate seals have since been repaired. In addition to restriction of daytime pumping, the blueback herring protection system was improved by reconfiguring and expanding the high-frequency sound repulsion system to provide greater acoustical coverage near the dam and expanding the system of pole-mounted lights used to attract blueback herring (and other species of fishes that attract to lights) away from the draft tube openings of the pump-storage units. The final component of the fish protection system for blueback herring was the elimination of a vortex in front of unit 8. This vortex appeared to attract and entrain large numbers of blueback herring into unit 8 and also interfered with the fixed-aspect hydroacoustics monitoring system. On 30-31 March 1995 a Unit 5 net catch expanded to a four unit total passage of approximately 400,000 fish. On 13-14 April, the CG agreed to a passage estimate (based on visual observations and extrapolations from Unit 5 netting) for Unit 8 of 227,000 fish in 4.5 hours and on 25-26 April the CG estimated (the recovery net partially failed) that 169,000 fish passed through unit 8 in 1.5 hours. The high entrainment rates, the inability of the monitoring system to characterize high entrainment, and scheduling considerations suggested that entry into Phase III be delayed until these problems could be solved. A rock berm, anchored to the shore and extending laterally for 300 feet into the channel, was constructed 600 feet downstream of the spillway of the dam to eliminate the vortex as a significant hydraulic feature downstream of the dam. Additional lights were installed along the South Carolina shore to attract blueback herring away from the pump units. Phase III data, collected with the full and complete protection system for blueback herring, did not produce a single high entrainment event for blueback herring as was observed on a number of occasions during Phase I or pre-Phase III sampling. Comparison of mobile hydroacoustics estimates for the upper arm of the Savannah River between 1995 and 1996 indicates that fish abundances were approximately equal between the two years. Similarity in fish abundance downstream of RBR dam in conjunction with substantially reduced entrainment from 1995 to 1996 suggests that the elimination of the vortex by the rock berm and the additional lights may be responsible for the reduction in spring time entrainment of blueback herring from 1995 to 1996.

Entrainment of striped bass and hybrid bass was reduced directly by installing a barrier that physically excluded fish larger than about 12 in. long from entry into the draft tubes. This barrier was further improved by reducing the gap around the edge of the barrier and the draft tube walls to no more than 2.0 in. Entrainment of these two species may also have been indirectly reduced by more efficiently redistributing blueback herring and threadfin shad away from the dam with the reconfigured sound repulsion system or the expanded lighting system. It is reasonable that a predatory fish would redistribute with the prey species. Entrainment of most species was also reduced by restricting project operation within 60 minutes

of official sunrise or official sunset. Phase II evaluations and consistent reductions of entrainment over Phase II and Phase III demonstrates that the fish protection system is providing a significant level of entrainment reduction and should be considered for continued implementation during commercial operation.

Table S-1. Summaries of Phase III sampling effort (in unit hours netted) compared to total Phase III pumping operation (in unit hours) and projected total plant pumping operation (in unit hours) for all pump units combined for each month of Phase III sampling.

Month	Total hrs. Netted Phase III	Total hrs. Pumping Phase III	Projected hrs. Pumping Wet Year	Projected hrs. Pumping Average Year	Projected hrs. Pumping Dry Year
January			0	389.7	690.8
February			33.1	314.9	629.7
March			0	194.9	478.3
April	66.3	159.9	34.3	308.6	497.1
May	66.9	364.4	35.4	389.7	549.1
June	65.5	256.5	68.6	497.1	634.3
July	73.5	604.6	194.9	690.9	744.0

November			0	394.3	685.7
December			35.4	442.9	690.9
Total Phase III	517.1	3129	802.9	3830.4	4632.5
Total Year	517.1	3129	871.4	5567.1	7807.9

Table S-2. Summaries of numbers and biomass for fish greater than or equal to 1.5-inches long based on Phase III netting months, estimated Phase III totals, projected wet water year (25% exceedance), projected average water year (50% exceedance), and projected dry water year (75% exceedance) for all species recovered during Phase III sampling. Note that shifts in relative abundance may occur between species. These shifts occur because the numbers of hours of pumpback operation is not constant and changes substantially across Phase III sampling and different water years. Data are not adjusted for passage survival. All projections include 2 & 3 standard deviations of the mean.

Table S-5. Annual projected entrainment obtained by expanding Phase III entrainment using an expansion factor defined as (Phase II annual entrainment) divided by (Phase II April October entrainment). These data are for all fish greater than or equal to 1.5-inches long and the data are not adjusted for passage survival. Missing values indicate that a species was not recovered during Phase II November-March and a 1.0 indicates that a species was not recovered during the April-October time period. The expansion factor was also applied to the mean hourly entrainment rate, by month, for projected entrainment for wet, average, and dry water years. Projections for entrainment of 2 and 3 standard errors of the mean are also provided.

Table S-6. Summaries of numbers and biomasses for fish greater than or equal to 1.5-inches long based on Phase III netting months, estimated Phase III totals, projected wet water year (25% exceedance), projected average water year (50% exceedance), and projected dry water year (75% exceedance) for all species recovered during Phase III sampling. Note that shifts in relative abundance may occur between species. These shifts occur because the numbers of hours of pumpback operation is not constant and changes substantially across Phase III sampling and different water years. All projections include 2 & 3 standard deviations of the mean. Data adjusted for passage survival.

Table S-6. (Concluded).

[illegible]

Table S-7. Annual projected entrainment obtained by expanding Phase III entrainment using an expansion obtained from Phase II data. The expansion factor was also applied to the mean hourly entrainment rate, by month, for projected entrainment for wet, average, and dry water years. Projections for entrainment of 2 and 3 standard errors of the mean also provided. Data adjusted for passage survival.

Table S-8. Summaries of numbers and biomass for different fish taxa greater than or equal to 1.5-inches long based on Phase III netting, estimated Phase III totals, projected wet water year (25 percent exceedance) for April to October, projected average water year (50 percent exceedance) for April to October, and projected dry water year (75 percent exceedance) for April to October for all species recovered during Phase III sampling corrected for survivorship. Size classes for black crappie and white perch are fingerling \leq 4 inch fish, intermediate >4 & ≤ 6 , and harvestable >8 . Size classes for striped bass and hybrid bass are fingerling \leq 4 inch fish, intermediate >4 & ≤ 8 , harvestable >8 & ≤ 14 , and desirable >14 inches. Round-off errors produce small discrepancies between this table and Table S-6.

* 1996 striped bass, hybrid bass, and white perch estimates are from the South Carolina DNR creel estimates and only include the area from the confluence of the Savannah and Broad Rivers downstream to Thurmond Dam. The Georgia DNR creel estimate which includes the area from the confluence of the Savannah and Broad Rivers upstream to Russell Dam had a combined striped bass, hybrid bass, white bass, and white perch harvest of 6,564 fish, but does not include species specific estimates. All other species are based on a combination of both states creel estimates.

Table S-14. Projected numbers and percentages of fish killed by entrainment during commercial pumped storage operation under dry (maximum), average, and wet (minimum) conditions and total fish numbers in JST. Total fish in JST obtained by combining arithmetic mean cove rotenone expansions (CR) excluding threadfin shad and blueback herring. Threadfin shad estimates were obtained from August 1996 mobile hydroacoustics survey (HAT). Estimates for adult blueback herring obtained from mark recapture study (MRB). TT=cell total. Entrainment numbers based on Phase III data, April to October.

Introduction

Background

The U.S. Army Corps of Engineers, Savannah District (SAS), develops and manages water resources on the Savannah River by constructing and operating reservoir projects. Richard B. Russell (RBR) Dam and Lake, begun in 1974, is the most recent of the Savannah River impoundments. The RBR project is located on the Savannah River between Hartwell Lake to the northwest and J. Strom Thurmond (JST) Lake to the southeast and forms part of the boundary of the states of Georgia and South Carolina. RBR dam has four reversible turbines and four conventional turbines. The reversible turbines can be used as pumps during periods of low power demand to replenish upstream storage for peak generation needs.

Experience at other hydropower projects, both conventional and pumped storage projects, in which an upstream project discharges into the headwaters of a downstream reservoir, indicates that the major effects of operation are experienced by the downstream reservoir. Pumped storage operation, in particular, can result in high entrainment rates of fish with attendant mortality. The mortality is primarily related to the differential distribution and abundance of fishes between the forebay and afterbay. During generation, water is released from the deeper parts of the upstream reservoir where the density of fishes is generally low. Therefore, turbine mortality during generation is generally negligible at large, hydropower storage projects. However, during pumped storage operation, water is pumped back from a shallow and narrow part of the downstream reservoir where the concentration of fishes can, at times, be high. The reduced conveyance area in the downstream reservoir produces higher water velocities during the pumping phase of pumped storage operation. This problem is most pronounced in tandem projects when blockage of spawning migrations by the upstream project may cause high, spring-time concentrations of fishes in the vicinity of the powerhouse. Alternatively, cool, oxygenated releases from the dam may attract cool water fishes such as blueback herring (*Alosa aestivalis*) and striped bass (*Morone saxatilis*). Fish may be unable to swim against the reversed flow at RBR dam and be eventually drawn into the units or fish could follow the flow lines to the dam until velocities become too high for them to escape from the entraining flow. Fish eggs and ichthyoplankton could also be entrained into the units.

JST Lake has an established sport fishery that is monitored and managed (which includes annual stocking) by the states of Georgia and South Carolina. A partial list of species important to the JST Lake fishery includes striped bass, white bass, crappie, several species of sunfish, sauger, white catfish, channel catfish, bullhead, hybrid bass, largemouth bass, yellow perch, gizzard shad, blueback herring, threadfin shad, walleye, and flathead catfish. In the FSEIS prepared prior to construction of the pumpback project, the District committed to evaluate potential turbine mortality of entrained fishes during pumpback at RBR and the potential impact on the JST fishery should be addressed.

Consequently, in 1986 the Corps of Engineers (CE) initiated an exhaustive study, the Richard B. Russell Fish Entrainment Study (RBRFES), to provide baseline data on the fish community of J. Strom Thurmond Lake, predict the potential for entrainment and fish mortality, develop fish protection measures, and monitor entrainment through the units. The District can compare total numbers of fishes entrained by species to their numbers within the lakes. It will be possible to assess impacts by direct comparison if numbers of entrained fish are small compared to population estimates (a few percent - the uncertainty in population modeling exceeds the effect of pumping operation) or by population modeling if the numbers of fish entrained are a significant percentage of the total in JST Lake.

Much of the information generated by the RBRFES and additional studies, such as water quality measurements and predictions, was used to fulfill commitments made in the Final Supplement to the Environmental Impact Statement (FSEIS) for RBR dam.

Recent Events

Studies conducted at RBR are closely coordinated among the states of Georgia and South Carolina, the U.S. Fish and Wildlife Service, the Department of Energy, and the CE. General study design and conduct is described under the Consent Order from the Charleston, SC, United States District Court, signed on 6 December 1991. A subsequent amendment, dated 3 April 1992, to the original Consent Order requires that the CE conduct specific tests and studies to complete mechanical and environmental testing of the units. These specific studies and their timing are described in the "Testing and Monitoring Plan pumped storage Operations Richard B. Russell Dam and Lake" (TMP), dated 23 March 1992, as attached to the amendment to the Consent Order. An additional amendment to the Consent Order, dated 27 February, 1996, made changes to the attached "Testing and Monitoring Plan" eliminating the requirement for hydroacoustic monitoring and increasing the number of net samples required per month for Phase III environmental testing. This amendment also permitted construction of a rock structure to correct the unit 8 vortex problem.

Testing and Monitoring Plan

The TMP identifies all environmental concerns and describes both water quality and fishery studies that the CE, State of South Carolina, State of Georgia, and National Wildlife Federation feel are required to quantify the impacts of pump-back operation on the environmental quality of RBR and JST lakes. All studies were conducted to be consistent with the following four general provisions of the TMP:

- a. A phased approach for bringing the units into operation which provides for a period of testing the units prior to committing them for dependable, commercial production.
- b. Installation and operation of a high frequency sound and light protection system.
- c. Extensive fishery monitoring to determine the impacts of pumped storage operation at RBR and the effectiveness of the fish protection system.
- d. Analysis of data from the monitoring plan to determine if additional fish protection measures and/or fishery mitigation is needed.

Activities to bring the units to commercial operation were separated into three phases. In Phase I, monitoring was employed to insure that no significant fish kills occurred during testing for mechanical and electrical certification. In Phase II, one or more pump-turbines were sampled at regular intervals during pumping operation and during more than four-unit conventional hydropower operation (2-4 days per month) to assess the impacts of fish entrainment and mortality. A second major objective of Phase II was to obtain an acceptable correlation between recovery net catches and the data obtained from fixed-aspect hydro-acoustics monitoring. This objective is carried forward into Phase III. This report summarizes data collected during Phases I and II and documents Phase III data collection activities to document fish entrainment and mortality during capacity pumpback with all four units. Water quality studies described in the TMP are submitted under a separate cover and are not described or discussed further in this report. The following environmental concerns (not involving water quality) were identified during preparation of the supplement to the RBR environmental impact statement as listed in the TMP:

- a. Entrainment of fish from JST Lake during pumpback operations.
- b. Entrainment of fish from RBR Lake during generation with more than four units.
- c. Changes in fish distribution resulting from pumped storage operations.
- d. Commercial and recreational access to the RBR tailrace and tailwater.

- e. Commercial and recreational fishing success in the RBR tailrace and tailwater.

Dam Description

Complete understanding of study results requires an understanding of the configuration of the dam. Richard B. Russell Dam is a concrete gravity dam with a total water line width in the afterbay of about 1200 feet. The dam consists of a powerhouse housing 8 turbines with a total width of about 640 feet on the Georgia side of the river and a spillway about 560 feet long on the South Carolina side of the river (Figure 1 [Figure 2-1 from FSEIS]). The turbines are numbered sequentially beginning with unit number 1 on the east side of the powerhouse and ending with unit number 8 nearest the spillway. Units 1-4 are conventional Francis units, and units 5-8 are Francis pump-turbines. The four 80-megawatt (MW) pump-turbines can be used as conventional power generators to supplement the four conventional power generators at the project during periods of peak demand or as pumps during periods of low demand to replenish upstream storage for later generation. During conventional generation, up to 648 megawatts of power can be generated as Richard B. Russell Dam releases up to 60,000 cfs into J. Strom Thurmond Lake (JST), the downstream reservoir. During pumped storage operation, up to a maximum of 30,000 cfs can be pumped from JST back into Richard B. Russell Lake.

Several conventions were employed throughout the report. The term "tailrace" refers to the rip-rapped portion of the Savannah River arm of JST and is equivalent to station 1. The tailrace extends from the foot of RBR Dam downstream for a distance of 450 m. "Tailwater" refers to the entire Savannah River arm of JST extending from the downstream end of the tailrace to the confluence with the Broad River (a distance of approximately 8 km). Tributary stations are stations that are located in the three major tributaries of JST: The Broad River, The Little River entering from the Georgia side of the lake and a separate river sharing the name Little River entering from the South Carolina side of the lake.

Study Participants

The RBRFES was partnered with both Federal and state agencies to incorporate regional expertise and to achieve consensus on study design, data handling, and interpretations. The RBRFES was managed by the SAS and executed by the U.S.A.E. Waterways Experiment Station in Vicksburg, MS. Baseline fisheries monitoring using conventional methods such as nets, electroshocking, and cove rotenone studies were performed by the National Biological Survey, Georgia Fish and Wildlife Cooperative Research Unit (Georgia Coop Unit) at the University of Georgia. The Coop Unit was also responsible for all "hands-on" processing of fish collected during conventional and pumpback full (entire intake plume is netted) or partial (approximately 50 percent of the intake plume is netted) recovery

net sampling and the conduct of net calibration studies to determine the recovery efficiency of the nets. Net design, deployment, retrieval, and storage were performed cooperatively by WES, SAS, and contractor personnel. The Coop Unit participated in analysis of all data collected by them. National Biological Survey, South Carolina Fish and Wildlife Cooperative Research Unit (Clemson Coop Unit) at Clemson University, South Carolina, developed estimates of commercial harvest of blueback herring. Mobile hydroacoustics data were collected and processed by WES staff and under contract Normandeau and Associates and Kleinschmidt, Inc. Fixed-aspect hydroacoustics data were collected and processed by on-site contract personnel with the assistance of WES. Further processing, analysis, equipment calibration, and QA/QC was performed by Aquacoustics, Inc. Elements of the fish protection system were identified by WES and designed and constructed cooperatively by WES and SAS personnel.

Study coordination and agency input were obtained through a Technical Coordination Group (CG) established under the TMP. The CG met monthly during Phase III to discuss study progress, study content, schedules, data, and other pertinent topics. A written log was used to transmit agency recommendations to the District Engineer. In case of disagreements within the CG, procedures were outlined by which agency concerns could be elevated to the District Engineer level.

Purpose and Objective

The purpose of the TMP was to develop a knowledge and data base sufficient to support decision-making regarding pumped storage operation at RBR dam. Specific Phase III study objectives were to evaluate fish entrainment and mortality during pumpback operation at as close to full commercial operation levels as feasible.

Phase III Study Summaries

Report contents and organization

The following studies represent each of the major components of the RBRFES. Detailed descriptions of the methods used for the studies can be found in Appendix A for entrainment studies (studies quantifying spatial and temporal patterns of entrainment) and Appendix B for baseline studies (studies presenting information on the abundance or spatial distribution of biological resources in either lake). Each of the study descriptions is preceded by a brief summary and is then presented in its entirety, that is, the introduction, materials and methods, results, and discussion are presented within each task area. Figures and tables for each task area are located at the end of the text for that specific task area. All appendices are bound under a separate cover.

1 Pumpback Full and Partial Recovery Netting

Summary

The only direct method for quantifying the passage of fish through a turbine is to employ nets to recover passed fishes. By agreement with the states, recovery netting was employed to estimate entrainment for impact assessment. Netting data are adjusted for net efficiency because nets capture fish of different species or sizes at different efficiencies. For example, the efficiency with which the recovery gear recovers 2-in. threadfin shad is only about 20 percent. To estimate the passage of 2-in. threadfin shad, the net sample must be expanded by a factor of 5.0 to account for this relatively low efficiency of recovery. Conversely, the recovery of fish greater than 10 in. approaches 100 percent so that minimal adjustments must be made to the netting data. The adjusted rate of passage (fish/hour) estimated from 16 net samples per month (with each unit sampled four times per month) is expanded by the number of pump unit hours of operation for that month to estimate total monthly passage during Phase III or to project entrainment based on that rate for different hydrologic conditions.

During Phase III, a total of 577,686 fish with a biomass of 3441 kilograms were collected by recovery nets. A total of 3,853,317 fish greater than or equal to 1.5-in. long having a biomass of 17,673 kg were estimated to have been entrained through the pump units during Phase III pumpback operation. However, passage survival studies demonstrated that not all fish were killed during passage. Incorporation of survival information reduces the numbers of fish killed by 4.9 percent but reduces the biomass of fish killed by 26 percent. For an annual cycle 10,078,432 fish could be reasonably expected (dry year entrainment) to pass through the dam and 8,067,489 could reasonably be expected to be killed during turbine passage.

During Phase III, threadfin shad (90.9 percent by number and 35.5 percent by biomass), blueback herring (6.4 percent by number and 33.7 percent by biomass), white perch (1.3 percent by number and 19.2 percent by biomass), and black crappie (0.7 percent by number and 6.1 percent by biomass) dominated the entrainment samples (Tables 1-2 and 1-3). These four species constituted 99.3 percent

by number and 94.5 percent by biomass of the entrainment samples. Entrainment percentages for other species important to the sport fishery of JST Lake were largemouth bass (0.027 percent by number and 0.0219 percent by biomass), striped bass (0.02 by number and 0.78 percent by biomass), and hybrid bass (0.01 percent by number and 0.73 percent by biomass). An additional 39 striped bass and 33 hybrid bass were estimated to have impinged on the bar screen veneers used to physically exclude large fish from the turbines.

Introduction

The only direct method for quantifying the passage of fish through a turbine is to employ nets to recover passed fishes. The rate at which fish are recovered by the nets must be corrected for net efficiency because nets are seldom 100 percent at recovering fishes (Table 1-1). Two types of netting were employed to recover fishes that passed through the turbines. A full recovery net covered the intake of pump-turbine unit number 5 and filtered most of the pumpback jet. A recovery barge connected to the furthest end of the net provided a platform from which fishes could be sampled in real time for identification, enumeration, and measurement. Fishes purposely inducted or entrained into the pump units could also be recovered for studies of immediate and delayed mortality. Full recovery netting is dangerous, complicated, and labor intensive compared to partial recovery netting (or fyke nets). Fyke nets were deployed into one of the two operational gate slots of each unit-the other bay was left unnetted as a safety measure to prevent pressure build up on the trash rack in case the fyke net on the netted bay clogged with debris or fish. The fyke nets were usually fished for one to five hours after which they were pulled and emptied. The fyke nets are much easier to deploy and retrieve but cannot be used for mortality studies or collection of real time samples. This section presents the species, size, and temporal composition of fish entrainment for pump storage operation at RBR dam.

Sampling Description

Phase III entrainment monitoring was conducted from 1 April 1996 to 31 October 1996. This time period was selected for sampling because long-term baseline fish sampling using a variety of gears indicated the time period of maximum biological activity downstream of Richard B. Russell Dam occurred during these months. The number of hours per month of recovery net sampling contrasted to the number of hours per month of Phase III pumpback operation is shown in Table 1-2 as well as the number of hours of operation projected for wet, average, and dry years. Note that the number of hours of sampling was generally constant varying from 66.3 hours in April to 84.4 hours in August. In general, recovery net samples were collected 16-18 times per month during Phase III with each of the four pump turbines being netted at least four times per month.

Phase III operation involved a total of 3129 unit hours of pumping operation at Richard B. Russell Dam between the months of April to October 1996. This total approximates an anticipated average water year of pumping operation of 3830 unit hours during these same months. Phase III operation was substantially greater (factor of 4) than anticipated wet year pumping operation of 803 unit hours and about 33 percent less than dry year condition pumping operation of 4633 unit hours for the same months. Consequently, the Phase III data set should be a good predictor of entrainment under average water year conditions (Table 1-2).

Phase III Netting Results - April through October 1996

During Phase III, a total of 577,686 fish with a biomass of 3441 kilograms were collected by full recovery netting (net covers all or most of exit jet) or partial recovery netting (net covers one of two bays of intake flow) during pumped storage operation. This estimate is corrected for net efficiency and for coverage for partial recovery netting. Recovered fish were expanded to estimate total power plant passage during pumping operation by calculating an arithmetic mean passage rate (fish/hour) from data obtained by recovery netting of the netted units and expanding the calculated rate by the total number of unit hours of operation for that month. During Phase III, sixteen net samples were collected per month with each sampling duration lasting a minimum of four hours. A total of 3,853,317 fish greater than or equal to 1.5-in. long having a biomass of 17,673 kg were estimated to have been entrained through the pump units during Phase III pumpback operation (Table 1-3). An additional 85 fish having a biomass of 56 kg were estimated to have impinged on the bar screen veneers that physically exclude fish greater than about 12 in. long from entering the draft tube openings during pumping operation (Table 1-9). Total impingement of fish on the bar rack veneers during Phase III sampling was estimated at 326 fish with a biomass of 172 kg. Impingement of fishes on the screens is a very minor component of impact on the fish community of J Strom Thurmond Lake resulting from pumped storage operation of Richard B. Russell Dam. Conventional generation passage was not monitored during Phase III studies. Prior to Phase III, the resource agencies agreed that monitoring activities should concentrate on the pumping phase of pumped-storage operation.

Adjustments for Survival

Passage survival studies for entrained fish during pumping operation found mortality ranging from 0.0 percent to 100.0 percent and was dependent upon the species tested and the month in which the test was conducted. Corrected for survival, a total of 533,327 fish having a biomass of 2327 kg were estimated to have been killed passing through the netted unit during Phase III (Table 1-4). A total of 3.66 million fish having a biomass of 13,016 kg were estimated to have been killed

by pumped storage operation during Phase III testing (Table 1-4). The addition of survival information changed the numbers of fish impacted by pumping by only 4.9 percent because the numbers are dominated by threadfin shad passed during the late summer and early fall when estimated turbine passage mortality of threadfin shad is near 100.0 percent. However, addition of survival information changed the biomass of fish impacted by pumping by 26 percent because passage of larger fish was greater during the spring months when estimated turbine passage mortality was reduced. Including survival into annual estimates of turbine passage produces a proportionally greater reduction in fish loss than including survival during Phase III. April 1996 survival data were applied to December, January, February, and March entrainment and June 1996 survival data were applied to November entrainment. These substitutions were based primarily similar water temperatures. Survival of passed fish is substantially greater during the cold water temperatures that characterize November through April (compare relative change in entrainment from Table 1-3 to Table 1-4 with relative change in entrainment from Table 1-15 to Table 1-19). For example, addition of turbine passage survival information changes Phase III loss estimates during dry year pumping from 5,204,911 to 4,842,477 (change of 7.0 percent). However, annual loss estimates change from 10,078,432 without considering turbine survival to 8,067,489 (change of 20 percent). Consequently, addition of survival information provides a substantial reduction in estimated total annual loss.

Turbine passage mortality estimates are conservative because fish passage mortality is not reduced by mortality resulting from capture, handling, transport, and holding of fishes (all components of control mortality) associated with conducting mortality studies. That is, for most species collected, recovered fish experienced stress from capture, handling, transport, and holding. These stresses are known to produce mortality of some recovered fish, but were not incorporated into turbine passage mortality estimates.

Species Composition of Pumpback Entrained Fish - April through October 1996

The following general trends in fish entrainment data are based on net data (net sample adjusted for efficiency and coverage) adjusted by survival information (Table 1-4). Note, however, that percentages that each species will contribute to total entrainment will vary by water year. This variation occurs because of the interplay between seasonal patterns of entrainment and monthly changes in pumping durations. The proportion that each month of pumpback capacity contributes to total annual pumpback capacity will change with water year (Table 1-2).

During Phase III, threadfin shad (90.9 percent by number and 35.5 percent by biomass), blueback herring (6.4 percent by number and 33.7 percent by biomass), white perch (1.3 percent by number and 19.2 percent by biomass), and black crappie (0.7 percent by number and 6.1 percent by biomass) dominated the entrainment samples. These four species constituted 99.3 percent by number and

94.5 percent by biomass of the entrainment samples. Entrainment percentages for other species important to the sport fishery of JST Lake were largemouth bass (0.027 percent by number and 0.0219 percent by biomass), striped bass (0.02 by number and 0.78 percent by biomass), and hybrid bass (0.01 percent by number and 0.73 percent by biomass). An additional 39 striped bass and 33 hybrid bass were estimated to have impinged on the bar screen veneers used to physically exclude large fish from the turbines.

Seasonal Patterns of Entrainment - April through October 1996

Phase III sampling included the critical spring and summer months when entrainment potential was high and fish activity was pronounced. There were several patterns observed in entrainment. These patterns are described in detail in Table 1-5 and summarized in Table 1-6. Entrainment of most species except threadfin shad was highest in the spring months. This corresponds to findings from the gillnetting results conducted as part of the baseline monitoring where the catch of species other than threadfin shad that exhibited a distinct spatial trend were most abundant near the dam in March, April, and May. This pattern was most evident for blueback herring, white perch, black crappie, striped bass, and hybrid bass. Threadfin shad were entrained in large numbers during the late summer and early fall (August through September) coinciding with the time period when juveniles have grown large enough to be effectively sampled by the recovery nets. Impingement of fishes on the bar rack veneer followed the same general seasonal pattern as was observed for entrainment of species other than threadfin shad. Impingement of large fish peaked in April and was negligible after May (Table 1-11(b)).

Unit-by-Unit Comparisons of Entrainment

Entrainment was summarized by unit to determine if any one unit tended to entrain more fish than other units (Table 1-7). No substantial differences in entrainment rate was observed except for Unit 5 April entrainment. Finer resolution to perform unit-by-unit comparisons is available from the fixed-aspect hydro-acoustics system results of which are documented later in this report.

Size Composition of Pumpback Entrained Fishes - April through October 1996

For purposes of comparability, fish size categories used to describe predicted entrainment in the Final Supplement to the Environmental Impact Statement are used to describe Phase III entrainment in this report. Size composition of

entrained fishes reflected species composition with 90 percent of entrained fishes occurring in the 1.6- to 3.5-in. size class (Table 1-8), the same percentage as the percent composition of threadfin shad (Table 1-4). Over 99.8 percent of Phase III entrained fish were less than 8.5 in. long (Table 1-8). The abundance of the next two size classes appears to be inverted with the 3.6- to 5.5-in. size class at 4 percent of the total being less abundant than the 5.6- to 8.5-in. size class at 6 percent (Table 1-8). The apparent inversion in abundance of the next two size classes reflects both the increased number of inch classes in the 5.6- to 8.5 in. size category and also reflects species composition of entrained fish. Blueback herring, the second most abundant species in the entrainment sample occur mostly in the 5.6- to 8.5-in. size class.

Size composition of key sport species entrained also was generally characterized by the smaller size classes (Table 1-8). The most commonly entrained sport fish was white perch. Of the 26,459 white perch estimated to have been killed passing through the turbines during Phase III, about 36 percent were of harvestable size (greater than 6.5 in. long) with the intermediate size class (4.5 to 5.4-in. fish) containing 58 percent of the sample. Less than 6 percent of the sample was in the fingerling size class. Similarly, total black crappie numbers killed by passage through the pump turbines was estimated at 20,104 with intermediate-size fish dominating the sample (84 percent of the total) and only about 9 percent of the total take of black crappie was in the harvestable size class.

Striped bass and hybrid bass entrainment was identified as a key issue early in project planning. Both state resource agencies stock hybrid and striped bass and both species are considered to be valuable sport fishes important to the economies of the local area as noted in the creel section of this report. Unlike the size distributions for black crappie and white perch, four size classes were used to characterize striped bass and hybrid bass entrainment (Table 1-8) so that entrainment of large fish (greater than 14 in. long), of interest to anglers and the resource agencies, could be described. A total of 595 striped bass were estimated to have been either killed passing through the dam (556) or impinged on the barrack veneer (39) during Phase III sampling (Tables 1-8 and 1-9). Of the total, 97 percent were less than 15 inches long (Table 1-8). Similarly, 84 percent of the total 279 hybrid bass estimated to either have been killed either passing through the dam (246) or impinged on the bar screen veneer (33) during Phase III sampling (Tables 1-8 and 1-9) were less than 15 in. long.

Phase III Entrainment Expanded to Annual Estimates

Phase III samples were collected from 1 April through 31 October, 1996. Consequently, entrainment during November, December, January, February, and March was not monitored during Phase III. Entrainment rates that could be reasonably expected during the unsampled months were estimated by reanalyzing Phase II data that were collected from August 1993 through August 1994 to

develop expansion factors that could be applied to the Phase III data. However, Phase II data were collected much less frequently than Phase III data with only four samples per month collected during the biologically active period and only two samples per month collected during the remaining months. This compares to 16 samples per month collected during Phase III. Consequently, any use of Phase II data to expand Phase III data to provide estimates of entrainment for November, December, January, February, and March should be viewed as a general guide only. The end of Phase II and the beginning of Phase III were separated by 19 months during which time the composition of the fish community may have changed and also the sampling effort differed significantly between the two phases.

Phase II expansion factors were developed by resummarizing Phase II data by monthly arithmetic passage rates (fish/hour) for each species recovered similar to the methods employed to analyze Phase III data. The resulting rates were multiplied times Phase III sampling and the expected monthly pumpback hours of operation to be expected for wet year, average year, and dry year pumping operations. Species-specific monthly totals of Phase II data were summed for the months of April through October (Table 1-12) to generate a Phase II data set that covered the same months as Phase III sampling. All months of Phase II sampling were then summed, for each species separately, to generate an estimate of total annual passage (Table 1-13). Expansion factors were then developed to determine the proportion of total annual entrainment that occurred during April to October for each species (Table 1-14). These factors were then applied to the Phase III entrainment totals for April to October to project annual entrainment for each species (Table 1-15). The annual expanded values for the worst case (dry year) projections (10,078,432) were numerically dominated by threadfin shad (9,316,803 - 92 percent), and blueback herring (433,431 - 4.3 percent), white perch (109,456 - 1.1 percent). No other species made up more than 1.0 percent of the total.

A similar procedure was used to estimate the numbers of fish that could reasonably be expected to be killed (as opposed to passing through the units) during an annual cycle, that is, estimates of fish passage survival were used to adjust the entrainment rates by those proportions of the fish that could survive entrainment through the pump units. Turbine passage survival rates obtained from Phase III were applied to Phase II data. April 1996 survival data were applied to December, January, February, and March entrainment and June 1996 survival data were applied to November entrainment. Revised tables were then generated for April through October (Table 1-16) entrainment and total annual entrainment (Table 1-17). From the revised tables, adjustment factors were generated (Table 1-18) that could be applied to Phase III entrainment data to project entrainment that could be reasonably expected for the different water years (Table 1-19). Projected worst case entrainment mortality of 8,067,489 per year, based on expansions of Phase III data, is dominated by threadfin shad (7,616,835 - 94.4 percent), blueback herring (313,069 - 3.9 percent), and white perch (56,175 - 0.7 percent). Projections revised for survival decrease substantially from entrainment estimates because passage survival appears to be inversely related to temperature. Winter time survival is substantially higher than summer time

survival because water temperatures in December through March are substantially lower than during most of Phase III sampling.

Note that projected numbers for various water years for Phase II and Phase III for the months of April through October are very close although biomasses deviate more substantially. The difference in biomass is probably related to the differential seasonal entrainment of threadfin shad between Phases II and III. Phase III entrainment was dominated by threadfin shad passage during August-September whereas these high rates were not as pronounced during Phase II. Consequently, the mean size of fish was greater in the summer of Phase II than in the summer of Phase III. This difference was most pronounced for the wet year projections where most pumpback operation occurs in the late summer. During the summer of Phase II, proportionally more blueback herring were entrained whereas in Phase III, proportionally more threadfin shad were entrained.

Additional Data Summaries

The TMP plan requires that summaries of Phase II findings be presented in the Phase III documentation. Entrainment totals based on arithmetic means from Phase II are presented in Tables 1-12 (April-October) and 1-13 (all months) along with water year expansions. These data are presented in greater detail in the Phase II Completion Report. Several instances were found where an entrainment sample was assigned to the wrong month. Misassigned data were corrected; however, the change will result in small differences between Phase II summaries presented here compared to other arithmetic summaries. The largest differences between summaries presented in this report compared to earlier summaries is caused by treatment of the data. As agreed to by the CG, the Phase II Completion Report presents summaries based on geometric means whereas the Phase II summaries presented in this report are based on arithmetic means, as the CG later requested.

Summaries from PrePhase III sampling from August 1994 to March 1996 are presented in Table 1-20 (not adjusted for turbine passage survival) and Table 1-21 (adjusted for turbine passage survival). PrePhase III data should be interpreted with caution because the data were not collected as part of a systematic monitoring program but instead were collected for a variety of purposes ranging from improving the hydroacoustic-net calibration to collecting flow field data. Also, entrainment rates for some samples of April of 1995 are underestimated because of net failure. Passage estimates when nets failed were recommended by the CG. Passage estimates for those months are as follows: On 13-14 April, the CG agreed to an estimated (based on visual observation and extrapolation from catch rates at Unit 5) passage through Unit 8 of 227,000 fish in 4.5 hours and on 25-26 April we estimated (the recovery net partially failed) that 169,000 fish passed through unit 8 in 1.5 hours.

Entrainment summaries for Phase I (before official beginning of Phase II) are presented in Tables 1-22 (not corrected for survival) and 1-23 (corrected for

survival). These two tables include all data for August 1993 except for 30-31 August, 1993 which is included in Phase II tables. As with the pre-Phase III sampling, these data must also be used with caution since they were not part of a rigorous sampling program, but rather were collected to test recovery gear or for similar reasons. Phase I data also include a number of daytime tests during which time entrainment rates were substantially higher than during nighttime testing. By agreement, day time testing and operation of pumped storage was suspended.

A listing of all data along with monthly standard error estimates are presented in Tables 1-24. These calculations combine data from all units during each month in order to calculate a sample mean and measure of dispersion. As directed by the CG, mean entrainment rate was obtained as the grand mean of the mean of hourly entrainment rates for each unit. Both methods will produce the same result if each unit is sampled an equal amount for each month. However, neither sampling duration nor sampling location was exactly uniform for Phase III. Consequently, the means obtained for calculating the measure of dispersion will vary slightly from the mean entrainment rates used to summarize entrainment. For purposes of consistency, values for dispersion about the mean (i.e., the standard errors tabulated in Table 1-24) were added back to the mean entrainment rate calculated by weighing each unit equally. As recommended by consultation between WES statistician and Clemson University, the mean ± 2 and 3 standard deviations were used as an interval measure for the entrainment data in lieu of confidence limits. The mean ± 2 and ± 3 standard errors has at least a 75% and a 89% chance, respectively, of including the population mean.

Table 1-1. Monthly full recovery (a) and partial recovery net (b) calibration estimates used for entrainment by species group and size group.

Table 1-4. Summaries of numbers and biomasses for fish greater than or equal to 1.5-inches long based on Phase III netting months, estimated Phase III totals, projected wet water year (25% exceedance), projected average water year (50% exceedance), and projected dry water year (75% exceedance) for all species recovered during Phase III sampling. Note that shifts in relative abundance may occur between species. These shifts occur because the numbers of hours of pumpback operation is not constant and changes substantially across Phase III sampling and different water years. All projections include 2 & 3 standard deviations of the mean. Data adjusted for passage survival.

Table 1-5. Comparison of mean monthly species entrainment rates (number/hour) for pumpback units. Rates for units 6, 7, & 8 are doubled to expand for unsampled bay sampling rate of 0.0 indicates no members of that species were collected for that unit. Data have not been corrected for turbine passage survival.

Table 1-8. Summaries of numbers and biomass for different fish taxa greater than or equal to 1.5-inches long based on Phase III netting, estimated Phase III totals, projected wet water year (25 percent exceedance) for April to October, projected average water year (50 percent exceedance) for April to October, and projected dry water year (75 percent exceedance) for April to October for all species recovered during Phase III sampling corrected for survivorship. Size classes for black crappie and white perch are fingerling \leq 4 inch fish, intermediate >4 & ≤ 6 , and harvestable >8 . Size classes for striped bass and hybrid bass are fingerling \leq 4 inch fish, intermediate >4 & ≤ 8 , harvestable >8 & ≤ 14 , and desirable >14 inches. Round-off errors produce small discrepancies between this table and Table S-6.

Table 1-14. Summary of Phase II data collection over 12 month period from August 1993 to August 1994. Ratios represent the proportion of the catch made in the months of April, May, June, July, August, September, and October compared to the catch for the full annual cycle. Values not corrected for passage survival. Missing values indicate that a species was recovered in only one of the two Phases of sampling.

Table 1-16. Summaries of numbers and biomasses for fish greater than or equal to 1.5-inches long based on all Phase II months, estimated Phase II totals, projected Phase II totals, projected wet water year (25% exceedance), projected average water year (50% exceedance), and projected dry water year (75% exceedance) for all species recovered during all months of Phase II sampling. Data adjusted for passage survival.

Table 1-18. Summary of Phase II data collection over 12 month period from August 1993 to August 1994. Ratios represent the proportion of the catch made in the months of April, May, June, July, August, September, and October compared to the catch for the full annual cycle. Data corrected for passage survival. Missing values indicate that a species was recovered in only one of the two Phases of sampling.

Table 1-19. Annual projected entrainment obtained by expanding Phase III entrainment using an expansion obtained from Phase II data. The expansion factor was also applied to the mean hourly entrainment rate, by month, for projected entrainment for wet, average, and dry water years. Projections for entrainment of 2 and 3 standard errors of the mean also provided. Data adjusted for passage survival.

Table 1-21. (Continued). Summaries of netting data collected during Phase II (August 1993 to August 1994), PrePhase III (September 1994 to March 1996). Comparison of mean monthly species entrainment rates (num/hour) for pumpback units. Rates for units 6, 7, & 8 are doubled to expand for unsampled bay. Sampling rate of 0.0 indicates no members of that species were collected for that unit. Data adjusted for survival.

Table 1-22. (Continued). Summaries of netting data collected during Phase I monitoring (December 1992 to July 1993). Comparison of mean monthly species entrainment rates (num/hour) for pumpback units. Rates for units 6, 7, & 8 are doubled to expand for unsampled bay sampling rate of 0.0 indicates no members of that species were collected for that unit. All of August 1993 data are included in this summary. Phase II summary includes only 30-31 August 1993. Data not adjusted for survival. 1 May, 1993 was the final daytime test.

2 Conventional Generation Netting

Summary

During pumped-storage operation, power is purchased during periods of reduced demand (usually at night or on weekend days) and used to pump water back into the upper reservoir for power generation when demand for power increases. The stored water supplements inflows into the watershed above the dam and therefore can considerably increase the power generating capacity of the dam. The increase in generation capacity resulting from pumping operation can also result in increased entrainment of fish from Richard B. Russell Lake. No samples were collected of fish passage through the pump units during conventional generation as part of Phase III sampling; however, substantial netting was conducted prior to entry into Phase III. These samples were collated by month and used to estimate entrainment for fish lost during conventional generation. Some of these samples were of short duration or collected when only a single unit was in operation, but can be used to estimate species composition and timing of entrainment. Analysis of spring time passage data for 1995 indicated that entrainment rates estimated for tests lasting one hour ($n=13$) had a significantly ($p=0.00043$) higher entrainment (413 vs 167 fish/hour) than four hour tests ($n=14$). Netting during conventional generation when more than one unit was generating proved to be difficult because of unpredictable cross currents that formed during multi-unit generation.

Conventional generation entrainment generally mirror stratification patterns in Richard B. Russell Lake. During non-stratification periods, entrainment can be high, particularly during the time period of threadfin shad winter kill. For example, mean entrainment rates of 7227 fish/hour were observed in February, most of which were threadfin shad (95.6 percent). However, during stratification periods entrainment was generally low (less than 100 fish/hour) because the centerline depth of the intakes tended to be below the thermocline. As a proportion of total hourly rate over the year, Clupeids comprised 94 percent of entrainment, with threadfin shad comprising 87.3 percent of entrainment followed by blueback herring at about 6.7 percent of entrainment by number. No sport fish comprised more than 1.0 percent of entrainment. Projected annual water year totals trends

follow pumped-storage entrainment trends with the highest entrainment for conventional generation, that can be attributed to the addition of pumped storage units, occurring during a dry year (5,918,426 annual entrainment compared to a wet year annual entrainment of 2,015,597).

Conventional Generation Netting

Conventional generation passage was not monitored during Phase III studies. In lieu of conventional generation monitoring during Phase III, the results of netting surveys conducted prior to Phase III were employed to estimate conventional generation entrainment. These historical data are presented here to generally depict entrainment rates that would have been reasonable to expect during Phase III conventional generation monitoring and during months not included in Phase III sampling. Conventional generation full recovery netting was restricted to unit 5. Each draft tube is separated into two bays by a splitter wall. Each bay was fished with a separate net attached to the trashracks. While the entrainment summaries probably represent general trends, the summaries are based on uneven sampling effort across months and years and there are no corresponding population estimates available against which to assess conventional generation entrainment. The conventional generation data should be used with caution because in some cases the netting summaries represent passage when only a single unit was running in conventional generation mode. Before entering into Phase III, the CG agreed that data collected prior to Phase III would be used to characterize entrainment during Phase III.

The baseline condition for monitoring was considered to be the plant capacity prior to installation of the pumped-storage units. That is, impact of conventional generation was defined as the amount of extra power plant capacity that was provided by the pump turbines. The contribution of pumped-storage operation to total plant capacity was obtained by running the hydrologic planning model, HEC-5, used by Savannah District to develop long term operational guidelines for the system under two different scenarios. The model predicts discharge at the dam in terms of average hourly discharge for each month. For scenario 1 the monthly average hourly discharge was calculated without the presence of the pumped storage units. For scenario 2 the monthly average hourly discharge was calculated assuming that the four pump-turbines were available to replenish upstream storage. The monthly discharge output was converted to unit hours of operation per month because the entrainment data is presented as a monthly mean hourly entrainment rate. To convert monthly mean hourly discharge to unit hours of operation the following formula was used:

$$\text{UNIT HOURS}_{\text{month } i} = \text{TOTALQ}_{\text{month } i} / \text{UNITQ}_{\text{hour}}$$

where

UNIT HOURS_{month i} = NUMBER OF UNIT HOURS OF OPERATION
FOR MONTH_i

TOTAL Q_{month i} = TOTAL MONTHLY DISCHARGE CALCULATED AS MEAN AVERAGE HOURLY
DISCHARGE X 3600 SECS HOUR⁻¹ X 24
HOURS DAY⁻¹ X DAYS MONTH_i⁻¹

and

UNIT Q_{hour} = FLOW CAPACITY OF ONE UNIT PER HOUR
CALCULATED AS MEAN HOURLY UNIT
DISCHARGE (7200 FT³ SEC⁻¹) X 3600 SEC HOUR⁻¹

For example if the model predicts an average hourly discharge for May of 7935 then the number of unit hours of operation is calculated as:

$$\begin{aligned}\text{UNIT HOURS}_{\text{May}} &= (7935 \text{ ft}^3 \text{ sec}^{-1} \times 3600 \text{ sec hr}^{-1} \times 24 \text{ hours day}^{-1} \\ &\quad \times 31 \text{ days month}^{-1}_{\text{May}}) / (7200 \text{ ft}^3 \text{ sec}^{-1} \times 3600 \text{ sec hr}^{-1}) \\ &= 2.1253 \times 10^{10} / 2.59 \times 10^7 \\ &= 819.95 \text{ unit hours month}^{-1}\end{aligned}$$

The difference between scenario 2 and scenario 1 (as unit hours of operation) was the amount of additional conventional generation capacity that was provided by pumping operation as unit hours of operation. The formulation was tested on Phase III conventional generation durations as a check on computational accuracy (Table 2-1). Note the generally close agreement between predicted and actual conventional generation operational durations as unit hours. Table 2-2 presents the conventional generation operation projections that were used to expand hourly entrainment rates obtained from netting data to predict the effect of pumping operation associated with different water years. The wet and dry year conditions were determined by averaging the 17 wettest and driest years in a 69 year period of record. The average condition was determined by the average of all 69 years. This new formula differs from the one used in previous draft and quarterly reports. The change was made because the previous formula was a poor predictor of actual operation.

Mean monthly (Table 2-3) and annual (Table 2-4) entrainment rates (fish/hour) by species for conventional generation netting are presented to provide an estimate of species composition of entrainment. Entrainment is dominated by threadfin shad (87.3 percent), blueback herring (6.6 percent), and yellow perch (4.2 percent). These three species together comprise 98 percent of entrainment by hourly rate. Conventional generation entrainment results generally mirror stratification patterns in Richard B. Russell Lake. Entrainment of sport fishes during conventional generation is relatively low for both the Phase III months and non-Phase III months. Phase III passage totals are generally low (Table 2-5) and are not of the same magnitude as Phase III pumpback passage. However, passage totals during non-Phase III months of November, December, January, February, and March are

substantially higher than during the Phase III sampling (Table 2-6). Considerable passage of fishes during the winter is common at hydropower dams, particularly for threadfin shad. Mortality of threadfin shad is common as the summer boom of threadfin shad is substantially reduced during winter die off (Table 2-3, see January and February rates). However, during stratification periods entrainment was generally low because the centerline depth of the intakes tended to be below the thermocline. Clupeids comprised 93 percent of entrainment with threadfin shad comprising 87.4 percent of entrainment followed by blueback herring at about 6.6 percent of entrainment by number (Table 2-4). No direct population estimates are available for threadfin shad and blueback herring as were performed for JST Lake. However, cove rotenone data were available to allow a comparison of the abundance ranking of threadfin shad and yellow perch in the two reservoirs. From the cove rotenone data, threadfin shad are the most abundant fish in RBR Lake. Entrainment of sport fishes during conventional generation is relatively low for both the Phase III months and non-Phase III months compared to pumpback entrainment. For example, only 72 striped bass, 304 hybrid bass and 14,075 black crappie are projected to be entrained by worst case conventional generation over an annual cycle compared to 2,789 striped bass, 2,134 hybrid bass, and 69,465 black crappie during worst case pumpback operation. These comparisons are not adjusted for survival although it is probable that survival during conventional generation is at least as great as during pumping operation. The runner blades are less likely to physically damage fishes by direct contact during conventional generation passage. During conventional generation the fish and runner blades are both moving at the same speed, unlike during pumpback when the fish are more likely to contact the runner blades. Sport catch in RBR Lake was summarized so that entrainment losses could be contrasted to commercial harvest (Table 2-7).

Projections of entrainment for the different water years show that entrainment combined for Phase III and non-Phase III months is approximately the same rate and species composition as entrainment during pumping operation. Projected water year entrainment totals for conventional generation follow the trends identified for pumped-storage operation with the lowest entrainment that can be attributed to the increase in plant capacity from pumped-storage operation occurring during a wet year (2,015,597 annual entrainment) compared to a dry year (5,918,426 annual entrainment).

3 Pumpback Ichthyoplankton and Larval Fish

Sampling

Summary

Many fish release their eggs into the water where they either drift with the current or adhere to rocks or other substrates. These eggs hatch into weak-swimming larvae (young fish having a discernible yolk sac). These younger life stages of fish, because they cannot efficiently propel themselves, are particularly susceptible to entrainment. Entrainment of ichthyoplankton by RBR Dam was identified as a concern by the CG.

Ichthyoplankton entrainment was estimated during Phase III by collecting water directly from the draft tubes of the dam by gravity feed from piping previously installed to house pressure sensors. During pumpback operation water from these pipes was sieved through a fine mesh net to separate entrained ichthyoplankton and other coarse particulate matter from water passing through the pump units. Ichthyoplankton were keyed to the lowest possible taxonomic level. Due to damage during collection, some fish could only be keyed as low as the family level. Mobile trawl samples also were collected in the RBR tailwater to estimate ichthyoplankton temporal and spatial trends. Samples were collected at four sites weekly using a fine mesh net towed from a boat. Mobile trawl sampling indicated that the ichthyoplankton distribution was patchy, and densities were in the RBR tailwater (about 1/100m³). Ichthyoplankton densities were substantially higher (about 50/m³) in Russell Creek, a small tributary of JST that discharges into a bay near the dam.

Arithmetic mean ichthyoplankton entrainment for Phase III of 124,564,935 larval fish was dominated by clupeids (111,401,435) including blueback herring, threadfin shad, and gizzard shad. Threadfin shad were the most abundant clupeid with an estimated total of 54,806,786. Projected maximum ichthyoplankton entrainment for dry year pumping was estimated at 266,858,067. A lake wide population estimate was not possible due to limitations in the data collected. However, a point estimate of the number of larval fish in the lake at any one time during a month was calculated. This estimate was compared to a daily estimate of the number of larval fish entrained by the dam in a month. Estimated percent of

larval fish, by group, during phase 3 varied from 0.002% for crappie to 1.778% for yellow perch. Estimated maximum ichthyoplankton entrainment during a dry year was projected between 0.005% and 3.367%, depending on the species.

Introduction

Ichthyoplankton (fish eggs and larvae having a discernable yolk sac) are particularly susceptible to entrainment because they cannot efficiently propel themselves. Entrainment of ichthyoplankton by RBR Dam was identified as a concern by the CG. Ichthyoplankton entrainment was estimated from net samples collected during pumpback operation at Richard B. Russell Dam from April-September 1996. The significance of ichthyoplankton entrainment was assessed by comparing entrainment to a point estimate of lake wide ichthyoplankton abundance available from 1987, 1988, and 1989.

Methods

See Chapter VIII of the "Phase III Testing and Monitoring Data Collection and Handling Standard Operating Procedures" provided as Appendix A to this report for the details of sampling. The following text generally summarizes sampling procedures.

Tailwater trawl

Tailwater trawls were collected weekly from April-August 1996. Thirty minute collections were made at each of four stations using a .5 m-500 μ mesh net. Sampling station locations were identical to locations used during 1987-1989 surveys. Station 1 paralleled the buoy line below the dam. Station 2 was about one mile downstream of the dam with station 3 located about 2.5 miles downstream of the dam. Station 4 was in Russell Creek, a small tributary of JST Lake within about 1.0 miles of the dam.

Analysis

Entrained larval fish

Hourly estimated entrainment of ichthyoplankton was calculated using the arithmetic mean of the number of fish collected per hour in the samples. The sample estimate was then expanded for the entire amount of water passing through the dam per hour. Monthly estimates were then calculated from the number of hours pumped during the month. Projections of entrainment for minimum, average, and maximum pump years were obtained by multiplying the monthly Phase III hourly

entrainment rate by the number of hours of pumping estimated for each water year. A point estimate for each month was calculated by multiplying the hourly entrainment estimate by the number of pump hours in the month and dividing that by the number of days in the month. This estimated the mean daily entrainment of ichthyoplankton for a month.

Lake wide larval fish tows

Due to the dynamics of larval fish and limitations in the larval fish tow data collected, a realistic lake wide larval fish population estimate is not possible for comparison with entrainment estimates at RBR dam. A point estimate of mean monthly larval fish abundance in JST was estimated for each month data was collected. Fish, in most cases, were grouped by family. Groups not sampled at the dam during phase III were not included in the comparison. Sampling in 1987-89 ended in mid-July therefore, no August comparison was made.

A monthly mean point estimate was calculated by summing the number of larval fish collected, by group, and dividing by the total volume of water sampled. This number was then multiplied by the volume of the lake, 3,023,300,000, provided by Jerry Germann.

Results

Estimated hourly and monthly ichthyoplankton entrainment estimates are provided in Table 3-1 and Phase III totals and projections are presented in Table 3-2. Only larval fish are included in these estimates, since no eggs were collected in samples. Estimated monthly entrainment and ± 2 and 3 standard errors are provided in Tables 3-3, 3-4, 3-5, and 3-6 for Phase III, wet year, average year, and dry year, respectively. Due to damage that occurred during netting many clupeids could not be identified below family level. Figure 3-1a, 3-1b, and 3-1c present timelines of estimated numbers of larval fish collected per hour by species from April-September. Figure 3-2a, 3-2b, and 3-2c show the expanded estimated number of larval fish collected per hour. The expansion factor used to expand the netted volume of water sampled to the volume of water passing through the dam was between 120,000 and 134,000.

The number of larval fish collected in tailwater trawls was considerably less than observed in 1987 through 1989 varying from less than one/100m³ in the tailwater, to about 50/m³ in the Russell Creek tributary (Figure 3-3). A similar trend was seen in 1987 and 1988 (Table 3-7).

Discussion

Composition of ichthyoplankton collected during 1993 and 1994 (Table 3-8) was similar to collections in 1996. More species were collected in 1996, however, probably due to a more efficient, and increased, sampling effort.

Larval fish entrainment at RBR dam was estimated at 124,564,935 for Phase III. Projected entrainment estimates range from 26,732,961 (wet year) to 266,858,067 (dry year) (see Ichthyoplankton Entrainment section).

There were differences in tailwater ichthyoplankton densities between the 1987-1989 surveys and the 1996 survey. Phase III operation of RBR Dam involved considerably more generation and pumpback than during the surveys of the late 1980's. Consequently, the constant flushing of the tailwater by RBR dam would reduce ichthyoplankton densities. Zimpfer (1990) indicates that operation of RBR dam was responsible for the decrease in ichthyoplankton near the dam.

A mean monthly point estimate and combined mean were calculated for 1987-1989 for each group of fish (Table 3-9). The point estimate of number of larval fish entrained was divided by the point estimate of larval fish in the lake to arrive at an estimate of percent entrainment. Estimated entrainment for Phase III varied from 0.002% for crappie in May to 1.778 % for yellow perch in May (Table 3-10). Estimates ranged from 0.0003% to 3.367% for dry, average, and wet years (Table 3-11, 3-12, 3-13).

Note: The lake wide population estimate of 160 billion larval fish provided in the earlier copy of this report was estimated from calculations in the SEIS. The mean larval fish estimate for JST in 1987-89 was multiplied by the number of days larval fish were expected to occur during the year and divided by 3.5, the recruitment rate of larval fish stated in the SEIS and Phase 2 reports.

Disclaimer

The arithmetic mean values and the standard errors associated with them in this report should be used with caution. The data used for this section is not normally distributed and is negatively skewed.

Table 3-1. Estimated ichthyoplankton entrainment during April-September 1996 at RBR dam, and estimated entrainment for dry, average, and wet years, using arithmetic means.

4 Pumpback Fish Mortality Studies

Summary

Fish survival is an important aspect of assessing turbine passage. Fish passing through the dam experience numerous conditions ranging from pressure changes to contact with the turbine blades. Mortality studies were employed to determine the effects of passage on fish survival. Two separate methods were used to estimate fish mortality: (1) Collect entrained fish as they pass through the dam; (2) Hold control fish and inducted fish, collecting them after passage. The first method provides a conservative (over) estimate of mortality because transport and handling stress increase mortality estimates. After collection, the fish were held for 48 hours to assess survival. In the first method, fish are handled during recovery, transported, and held in water that is of a slightly different water quality. There are stresses on the fish associated with the procedures that will result in fish mortality. The second method provides a more realistic estimate of mortality since groups of control fish are used to subtract out experimental mortality caused by transport, handling, and the recovery net. Reliable estimates of mortality for many of the inducted fish experiments could not be used due to high mortality among control fish, due mainly to the poor condition of fish received from the hatchery. Most mortality estimates in Phase III were obtained from entrained fish.

Mortality estimates ranged from 0.0 to 100.0 percent depending upon the species and time of year. Mortality rates ranged from 65.0 to 100.0 percent for clupeids (blueback herring, threadfin shad, and gizzard shad), 29.5 to 85.0 percent for sunfish and crappie, 0.0 to 28.5 percent for catfish, 17.8 to 72.1 percent for yellow perch, and 45.3 to 81.8 percent for *Morone* sp. (striped bass, hybrid bass, white bass, and white perch). A significant positive relationship between water temperature and mortality was found for clupeids, catfish, and *Morone* sp. (as water temperature increases mortality increases). This relationship was not observed for sunfish and crappie, and yellow perch. The lack of correlation for sunfish and crappie is probably due to damage to the fish caused by the full recovery net. A majority of entrained sunfish and crappie were descaled on one side of their body. Heavy scale loss was also found with control bluegill sunfish inducted directly into the net without going through the turbines, also suggesting a net

effect. The lack of correlation between yellow perch mortality and water temperature is probably due to pressure sensitivity. Yellow perch are highly sensitive to pressure changes resulting in rupture of the swim bladder or kidneys. The majority of dead yellow perch in the study had everted swim bladders.

Introduction

Fish survival is an important aspect of assessing turbine entrainment. Survival estimates of fish passing through the turbines during pump storage operation at Richard B. Russell Dam were estimated from mortality experiments using entrained and induced fish. Mortality studies were performed to determine the proportions of fishes that could survive passage through the turbines during pumping operation. These studies can be separated into two categories depending upon the hardiness of the target fish species. For relatively hardy species, such as catfishes and bluegill, marked fish were induced into the units through 4-in. food processing hoses and recovered using the full recovery netting system. Multiple controls were performed by inducing fish into the penstocks (all effects of induction system but without turbine passage) or holding marked fish without induction to determine the effects of marking and handling. For fragile species such as threadfin shad and blueback herring, entrained fish were recovered at the recovery barge to determine immediate and delayed (recovered fish were held in tanks for 48 hours) mortality. Control tests could not be performed for fragile fish species because control mortality was 100 percent. Therefore, estimates of turbine passage mortality are conservative because they have not been adjusted for handling mortality.

Methods

See Chapter IX of the "Phase III Testing and Monitoring Data Collection and Handling Standard Operating Procedures" (Appendix A) guide for a complete description of the methods. Several changes were made, however, during the course of this study.

The induction control group (C2) was eliminated from the study. The unmarked control (C3) group was reassigned the C2 code. The pressured induction system was abandoned in favor of the trash pump since mortality was not reduced, fish retrieval was reduced, and human effort was increased. See Chapter XI of the "Phase III Testing and Monitoring Data Collection and Handling Standard Operating Procedures" guide for a description of the fish induction system. Test species within each grouping were interchanged (e.g., threadfin shad were used with, or instead of blueback herring).

Results

Inducted fish

Results of the fish induction experiments are provided in Table 4-1 and are divided by test date, repetition of the experiment, and size group.

Bluegill were tested in May and October. Mortality rates for the small fish varied from 11.1 to 52.4 percent and control mortality varied from 0.0 to 46.5 percent. Large bluegill in May developed a bacterial infection during pretest holding. Due to their poor condition and high control mortality, conclusions should not be made from this estimate. For large fish, mortality varied from 18.2 to 47.6 percent. Control mortality varied from 10.6 to 39.3 percent.

Channel catfish were tested in May, June, July, and September. The estimate for June should be ignored due to high control mortality. There was some size overlap of the September fish; however, most of the fish tested were 5 in. or smaller. Mortality rates for small catfish ranged from 0.0 to 5.6 percent. Control mortality varied from 0.0 to 5.6 percent, also. Mortality rates for large catfish varied from 0.0 to 18.2 percent. Control mortality varied from 0.0 to 18.2 percent, also.

Morone sp. were tested once at the beginning of April. Mortality rates for 5-6 in. fish varied from 29.3 to 52.0 percent and control mortality varied from 20.6 to 48.8 percent. Mortality rate for 7-9 in. fish was 100 percent and control mortality ranged from 0.0 to 7.1 percent. During pretest holding these fish developed an infection and were not in good condition. Due to the observed condition of these fish and the high mortality of the C1 fish a reasonable mortality estimate cannot be obtained from this experimental group.

Yellow perch were tested once in the middle of April. We were unable to obtain enough fish of either size group suggested in the protocol so the two groups were combined. Mortality rates varied from 26.3 to 90.1 percent and control mortality varied from 12.0 to 82.4 percent.

Entrained fish

Test results for the entrained fish mortality experiments are provided in Table 4-2. Species, size, and number of replications collected was dependent on fish entrainment for the given night.

Forty-eight hour mortality estimates for clupeids (blueback herring, threadfin shad, and gizzard shad) ranged from 20.0 to 100 percent. Mortality rates for catfish varied from 0.0 to 28.6 percent. Mortality ranged from 25.0 to 100 percent for bluegill and black crappie. Mortality for *Morone* sp. and yellow perch varied from 12.5 to 83.3 percent and 0.0 to 94.1 percent, respectively.

Analysis

There was significant size related mortality for clupeids and for bluegill/crappie in May ($p < 0.05$). In both cases large fish survival was higher than for small fish. Significant relationships were not found in other months, or for other species.

Calculations were also conducted to determine if there was a significant difference between mortality estimates of entrained fish, inducted fish, and control fish. Because of similarities in temperature profiles, data from the months of April-June and July-October were combined and size groups combined to ensure large enough sample size. There was a significant difference ($p < 0.05$) for *Morone* sp. and bluegill/crappie in April-June and for catfish and bluegill/crappie for July-October. There was not a significant difference for catfish or yellow perch in April-June.

For entrained fish there was a significant positive relationship between water temperature and mortality rate for clupeids, catfish, and *Morone* sp. ($p < 0.01$) (Figure 4-1). There was not a significant temperature/mortality relationship for bluegill/crappie or yellow perch (Figure 4-2). There was a significant negative relationship between dissolved oxygen and mortality rates for clupeids, catfish, and *Morone* sp. This should be expected since there is a strong negative relationship between water temperature and dissolved oxygen concentrations.

Mortality estimates

Monthly mortality estimates as decided by the Coordination Group are provided in Table 4-3. Mortality rates are developed from either entrained or inducted fish tests and comments are provided next to the mortality rate of how the estimate was derived if enough fish of the species and size group were not available for that month. See Chapter IX Part II of the "Phase III Testing and Monitoring Data Collection and Handling Standard Operating Procedures" guide for a complete description of criteria for choosing mortality estimates.

Table 4-4 provides a list of prior mortality tests and results.

Discussion

These results provide a conservative (over) estimate of mortality because all sources of stress and damage caused by the net, handling, and transport could not be eliminated. To provide a turbine related mortality estimate, it is necessary to reduce stress incurred due to the experimental protocol. This usually means reducing control mortality below 10 percent (Ruggles 1991). Except for catfish, this criterion was not met. The inability to reduce excess control mortality was the primary reason for use of entrained fish for passage mortality estimation.

Clupeids and bluegill/crappie were the only two groups where mortality was size-related, and occurred only in the May samples. For the other months, size-related mortality was not significant. For the clupeids, this was due to threadfin shad mortality being higher than mortality of the larger blueback herring. The size related difference for bluegill/crappie could not be explained.

Survival estimates for inducted *Morone* spp and bluegill/ crappie were higher in April-June than for entrained fish. Similarly, survival estimates for inducted catfish and bluegill/crappie were higher than for entrained fish in July through October. These increases in survival of inducted over entrained fish are a result of including control mortality into the estimates of passage mortality. Both the results and observations during the experiments indicate that handling of fish during capture, transport, marking, induction, and recovery in the nets inflated turbine passage mortality estimates.

Correlation between mortality and water temperature is expected. The lack of correlation for bluegill and crappie is probably due to damage to the fish caused by the full recovery net. A majority of entrained bluegill and crappie were descaled on one side of their body. The same was seen with inducted bluegill for both treatments. Since fish inducted from the penstock deck also were observed to have heavy scale loss it is likely the net had an increased effect on mortality, masking the temperature effect. The lack of correlation between yellow perch and water temperature is probably due to pressure sensitivity. Forge and Scott (1965) showed that yellow perch are highly sensitivity to drastic pressure changes resulting in rupturing of the swim bladder and kidney damage. Everted air bladders were observed on most yellow perch that died. No internal analysis was done. This pressure related injury was not seen with any other species entrained.

There was also a strong negative correlation between dissolved oxygen levels and survival of clupeids, catfish, and *Morone* sp. The lack of correlation for yellow perch and bluegill/crappie is the same as described for lack of correlation with temperature. Temperature and dissolved oxygen levels are strongly negatively correlated and probably have an additive effect on fish.

5 Baseline Fisheries Studies

Summary

Baseline studies using a variety of different collecting gears (because different types of fish are best sampled with different kinds of sampling gears) were performed to describe the species composition and temporal and spatial distribution of the fish community of J. Strom Thurmond Lake. The general objectives of baseline monitoring activities were to determine (1) the principal components of the fish communities in the two reservoirs; (2) spatial variation of fish communities in terms of species composition and biomass; (3) seasonal and annual variation in fish communities in terms of species composition and biomass; and (4) the uniqueness of the tailwater area immediately below Richard B. Russell Dam.

Baseline sampling included the following major tasks. Gillnetting, electrofishing and rotenone sampling were used to describe the fish communities and to assess spatial and temporal trends in abundance of fishes; Larval fish sampling was used to describe spatial and temporal patterns of fish reproduction; Zooplankton sampling was used to describe spatial and temporal trends in abundance of zooplankton; Purse seining was used to relate size distributions of fish with target strengths from hydroacoustics sampling; Telemetry was used to evaluate the spring and summer distribution of striped bass, hybrid bass, and sauger in the tailwater and to relate fish movements to operations at RBR dam. Lastly, draft tube sampling was used to determine the species, numbers and sizes of fish potentially susceptible to entrainment during pumpback.

The culmination of baseline sampling efforts shows that the highest biomass of fish occurs at station 1 during the period of March, April and May. In fact, this period encompassed all species that showed definable temporal trends in distribution. Numbers of all fish other than threadfin shad were also highest during these months. Peaks in threadfin shad abundance ranged from March to September for all gears, and numbers/net (or transect) were often very high. The "boom or bust" nature of threadfin shad catches suggests that potential entrainment (by number) could be high in any month between March and September. It is important to note that temporal predictions in entrainment are *relative* and do not imply that entrainment in other months will necessarily be low in terms of absolute numbers or biomass. Absolute numbers cannot be inferred from catch rate data.

Introduction

This report is intended to serve as a comprehensive resource of all sampling conducted as part of the baseline fisheries monitoring for the Richard B. Russell Fish Entrainment Study (RBRFES). For data previously reported, the methods and significant results are briefly paraphrased from the original reports and the appropriate references provided. References are also provided for research conducted outside the scope of the baseline monitoring.

Baseline sampling for the RBRFES was initiated on J. Strom Thurmond reservoir (JST) in 1986 and was dynamic over the eleven year study period. The sampling gears used, the locations of sampling, and the frequency of sampling changed over time in response to the changing informational needs and objectives of the RBRFES.

Baseline sampling occurred throughout J. Strom Thurmond reservoir (JST) from 1986 to 1990 to evaluate reservoir wide trends. From 1990 to 1996, sampling was limited to the upper end of the reservoir to monitor near-field trends below Russell dam. Also in 1990, sampling was initiated on the lower third of Richard B Russell reservoir (RBR) to monitor near field trends above Russell Dam.

The general objectives of baseline monitoring activities were to determine:

- a. What are the principal components of the fish communities in the two reservoirs?
- b. How do the communities vary spatially within reservoirs in terms of species composition and biomass?
- c. How do the communities vary seasonally and annually in terms of species composition and biomass?
- d. Is the tailwater area immediately below Russell Dam unique?

Baseline monitoring activities included gillnetting, electrofishing, cove rotenone sampling, larval fish and zooplankton sampling, purse seining, telemetry and draft tube sampling. General information obtained from each sampling gear is briefly described below. Specific objectives of each sampling method can be found in Nestler (1990) and Nestler (1991). Gillnetting, electrofishing and rotenone sampling were used to describe the fish communities and to assess spatial and temporal trends in abundance of fishes; Larval fish sampling was used to describe spatial and temporal patterns of fish reproduction; Zooplankton sampling was used to describe spatial and temporal trends in abundance of zooplankton; Telemetry was used to evaluate the spring and summer distribution of striped bass, hybrid bass, and sauger in the tailwater and to relate fish movements to operations at RBR dam. Purse seining was used concurrently with mobile hydroacoustics to provide information on species composition and size distribution of fish. Vertical

gillnetting was used to relate patterns of distribution to temperature and dissolved oxygen. Lastly, draft tube sampling was used to determine the species, numbers and sizes of fish potentially susceptible to entrainment during pumpback.

Methods

Rotenone sampling

Rotenone sampling was conducted on J. Strom Thurmond in 1986 and 1987. Sampling consisted of four coves in 1986 (Buoy 140, Bussey Point, Little River - S.C., and Murray Creek) and five coves in 1987 (Buoy 140, Bussey Point, Cliatt Creek, Little River - S.C., and Murray Creek). Data for 1985, 1990, and 1994 were obtained from the Georgia Department of Natural Resources (GADNR) in Serber table format. Figure 5-1 (all Section 5 figures and tables are in Appendix B) shows the approximate locations of each cove. All coves were mapped each year to estimate volume and surface area.

Rotenone sampling was conducted annually on Richard B. Russell from 1990 to 1996. Three coves were sampled each year in Richard B. Russell (Island Cove, Elbert Cove, and Dam Cove). Figure 2 shows the approximate locations of each cove. The three coves were mapped in 1990. Surface area estimates for each cove in subsequent years were calculated using the formula:

$$SA_{1990} + (SA_{1990} \times (\text{lake elev}_{\text{year } i} - \text{lake elev}_{1990}) \times 0.022222)$$

where

$$SA_{1990} = \text{Mapped Surface Area in 1990}$$

$$\text{lake elev}_{1990} = \text{lake elevation at time of mapping in 1990}$$

$$\text{lake elev}_{\text{year } i} = \text{lake elevation at time of sampling in 1991-1996}$$

0.022222 is a constant

This equation was derived from the area capacity curve for RBR. The relationship between surface area and lake elevation was approximately linear across the range of elevations encountered in August for the years 1990 to 1996 (473 to 478). The slope of the relationship was 0.022222 indicating that surface area increases by 2.2222 percent per foot of increase in elevation.

Procedures in 1985 and 1986 were consistent with those used by GADNR and GADNR personnel often provided assistance during sampling (on coves in Georgia). A block net was set across the mouth of the cove the evening prior to sampling, rotenone was applied the next day, and fish were picked up for two days.

Routine Gill Netting

Gill net sampling was conducted at eleven stations in JST from July 1986 to September 1988 (Figure 5-1). Stations 1-4 were sampled monthly while stations 5-11 were sampled approximately quarterly. Gillnetting effort at station 1 was increased in October of 1987 to include moratorium (non-generation) samples. From October 1988 to October 1996 stations 1-5 were sampled monthly. Gillnet sampling was conducted monthly at five stations (21-25) in RBR for the period of May thru October from 1990 to 1996 (Figure 5-2).

WES personnel sampled JST from February to June in 1986. However, the nets used were multifilament and configured slightly different than those used by GCFWRU. Therefore, these data were omitted from long term trend analyses.

Sampling effort for both lakes typically consisted of four experimental gill nets (replicates) at each station, except for non-moratorium samples at JST station 1 which consisted of two nets. All samples were overnight sets with durations typically in the range of 15 to 24 hours.

From July 1986 to February 1992, the experimental nets were 45.72 m × 2.44 m and consisted of six 7.62 m × 2.44 m panels. Mesh sizes (bar measure, mm) across the panels were 25.4, 38.1, 50.8, 63.5, 76.2 and 88.9. No effort was made to record the mesh sizes that fish were captured in. From March 1992 to October 1996, the experimental nets were 76.20 m × 2.44 m and consisted of ten 7.62 m × 2.44 m panels. Mesh sizes (bar measure, mm) across the panels were 9.5, 12.7, 19.1, 25.4, 38.1, 50.8, 63.5, 76.2, 88.9, and 101.6. The mesh size was recorded for each fish sampled.

Because meshes less than one inch were not used prior to 1992, the data were split into two data sets for analysis. The first set consisted of data from meshes that were 25.4 mm and larger (July 1986 to October 1996). The second set consisted of data from the 9.5, 12.7 and 19.1mm meshes (March 1992 to October 1996). Station groupings for JST analysis were determined by the RBR Coordination Group (CG) and were primarily based on proximity of the stations to Russell Dam and each other. For J. Strom Thurmond, the groupings were station 1 (tailrace), stations 2-4 (tailwaters), station 5 (Broad River) and stations 6-11 (downlake). For Richard B Russell, the groupings were stations 21-23 (downlake), station 24 and station 25. Stations 21-23 were pooled because of their close proximity to each other and Russell Dam (i.e., these stations would be the most impacted by immigration or emigration of fish from dam operations).

Electrofishing

Electrofishing samples were collected at eleven stations (consistent with locations for gillnet sampling) in JST from July 1986 to September 1988. Stations 1-4 were sampled monthly while stations 5-11 were sampled approximately quarterly.

From October 1988 to October 1996 stations 1-5 were sampled monthly. Electro-fishing samples were collected monthly at five stations in RBR (consistent with locations for gillnet sampling) for the period of May thru October from 1990 to 1996.

Sampling effort consisted of three permanent transects (replicates) of equal length (152 m) at JST stations 2-11 and RBR stations 21-25. These transects were randomly selected at the beginning of the study from 20 possible transects at each station. Sampling effort consisted of three longer transects at JST station 1. Replicates at station 1 were approximately 300 m each along the Georgia shoreline, the South Carolina shoreline, and along the dam face. Station groupings for analysis were the same as those for gillnetting.

Horizontal "Clupeid" Gill Netting

Horizontal clupeid netting was conducted from April 1989 to February 1992 on J. Strom Thurmond and from May 1991 to October 1991 on Richard B. Russell. Sampling effort consisted of two or four experimental gill nets (replicates) at each station. All samples were overnight sets with durations typically in the range of 15 to 24 hours. The experimental nets were 22.86 m × 2.44 m and consisted of three 7.62 m × 2.44 m panels. Mesh sizes (bar measure, mm) were 12.7, 19.1, and 25.4. The mesh size was recorded for each fish sampled.

Blueback herring, gizzard shad and threadfin shad were the targeted species of these nets with other fishes considered as incidental catch. However, catch of gizzard shad was generally low in these nets relative to nets with larger meshes. Therefore, analysis of catch was limited to blueback herring and threadfin shad.

Defining Principal Components of the Fish Community

The Index of Relative Importance (IRI) was used to define the species that were principal components of the fish community. Because of differential selectivity or gears, IRI scores were calculated for each gear. Each species IRI score within gear was calculated using the formula:

$$\text{Species IRI} = (\% \text{ by number} + \% \text{ by weight}) \times \text{F.O.}$$

where

% by number = the percent of total catch by number

% by wt = the percent of total catch by weight

F.O. = percent of samples that caught at least one fish of the species

Data analyses for these gears were limited to total catch and the top ten IRI species for each gear. Spatial and temporal trends were identified from plots of catch per unit effort (CPUE) by kilograms and numbers over time. Each page consisted of three graphs per station grouping: mean catch by month over the entire sampling period, mean catch by month with the median plotted as a measure of central tendency for the month, and coefficients of variations (CV's) for the monthly means. When evaluating seasonality of catch, ranges of the means and the medians were compared among months. Evaluations of size composition were based on the surer size categories used for the rotenone tables (see Section 1 of Appendix C). All fish collected were used to calculate size distributions by surber categories.

Ichthyoplankton Sampling

Ichthyoplankton sampling was conducted on JST from 1987 to 1989. Samples were collected in the channel at each station using a conical plankton net with a mouth diameter of 0.5m, a length of 1.8m, and 505 μ m mesh. Sample tows were stepwise oblique tows starting at 4 m deep and ending at the surface. Total time per tow was ten minutes (approximately 2.5 minutes at each 1 m depth interval). A flow meter was mounted in the mouth of the net to estimate total volume of water sampled. Four replicate tows were collected at each station. Stations were the standard stations in J. Strom Thurmond.

Zooplankton Sampling

Zooplankton sampling was conducted on JST from 1987 to 1989. Samples were collected in the channel at each station using a conical plankton net with a mouth diameter of 0.5 m, a length of 2.0 m, and 64 μ m mesh. Samples were vertical tows. The net was lowered to a depth of 4.6 m and raised to the surface with an electric winch. Total volume of each tow was approximately 0.9 m³. Four replicate tows were collected at each station. Stations were the standard stations in J. Strom Thurmond except for station 0 which is the Richard B. Russell forebay.

Telemetry

Telemetry studies were conducted in 1987 and 1988. Hybrid bass, striped bass, and sauger were collected primarily with gillnets and radio transmitters were surgically implanted or externally mounted depending on the size and the condition of the fish. Routine tracking was conducted by boat or plane twice per week in the tailwater area and once per week outside of the tailwater area using a scanning receiver and hand-held directional antenna. Tracking was also performed on a diel

basis (every 4 to 6 hours over 24 or 48 hour periods) in the immediate tailwater area (within 4 km of RBR dam).

Other Sampling Gears

Vertical gillnetting was conducted on JST in 1988 and 1989 to relate patterns of vertical distribution to temperature and dissolved oxygen. Sampling effort consisted of two or four vertical gill nets (replicates) at each station. All samples were overnight sets with durations typically in the range of 15 to 24 hours. The vertical nets consisted of two adjacent 1.8m panels that extended from the surface to the bottom. Mesh sizes (bar measure, mm) across the panels were 12.7 and 19.1. The mesh size and depth was recorded for each fish sampled.

Blueback herring and threadfin shad were the targeted species of these nets with other fishes considered as incidental catch. Therefore, analysis of catch was limited to blueback herring and threadfin shad.

Purse seine samples were collected in 1988 and 1989 concurrent with hydroacoustic samples at the base of Russell Dam. These data were collected to provide verification of species composition and size distribution to complement mobile hydroacoustics sampling. The protocol was to follow the hydroacoustics boat and deploy the seine (20 ft × 300 ft) when a large congregation of fish was found. Sampling effort (number of times the seine was deployed) was dependent on catch. The net was usually deployed until a minimum sample size of 100 to 200 fish was obtained. No effort was made to quantify total catch once the minimum sample size was obtained. When large numbers of fish were collected, fish were randomly subsampled for species composition and lengths. Because no attempts were made to standardize effort or quantify total catch, these data were not used to examine seasonality of catch.

Draft tubes at RBR were dewatered periodically to determine the species, numbers, and sizes of fish present and potentially susceptible to entrainment during pumpback. Draft tube sampling was conducted from 1988 to 1994, but the frequency of samples was variable. Draft tube gates were set in place before penstocks were closed to minimize the escape of fish as the water was removed. All fish remaining in the draft tube after dewatering were collected, identified, measured to the nearest millimeter and weighed to the nearest gram.

All Data

Section 1 of Appendix D provides all gillnet configurations used over the course of study. The actual number of samples (replicates) collected for each reservoir and gear is provided by month in Section 2 of Appendix D.

The accuracy of the digital data against the original field sheets was verified through a combination of computer programs and manual line by line proofing. All "questionable data" output by proofing programs were verified against the original sheets and approximately 90 percent of all data were manually proofed independent of the computer proofing. Therefore, most "questionable data" were verified twice.

After proofing, plots of weight versus length by species revealed a number of aberrant lengths and/or weights. These points represented very small percentage of the data and were considered field measurement errors. The magnitude of some of the points warranted correction prior to analysis or summarization of data by weights. Therefore, regressions of \log_{10} weight versus \log_{10} length were calculated for each species by reservoir and used to replace suspected field errors and missing weights. Essentially, as data were read into a working data set by SAS, fish weights that were 30 percent less than or 35 percent greater than the predicted weight (based on length) were replaced by the predicted weight. These bounds were fitted by eye to approximate the 95 percent confidence intervals about the regressions using all data. Section 3 of Appendix D provides the regression equations for each reservoir and species and plots of weight versus length for selected species.

Results

J. Strom Thurmond Reservoir

Rotenone sampling

The top 10 IRI species for this gear were: bluegill sunfish, threadfin shad, gizzard shad, largemouth bass, redear sunfish, warmouth sunfish, yellow perch, common carp, black crappie, and spotted sucker. These ten species accounted for over 91 percent by number and 82 percent by weight of all fish caught during the five years evaluated (Tables 5-1 and 5-2). The top 10 IRI species accounted for 84 percent, 76 percent, 88 percent, 81 percent, and 78 percent of the total biomass sampled in 1985, 1986, 1987, 1990, and 1994, respectively (Table 5-3).

Total fish biomass varied considerably across the five years (range 70 to 255 kg/ha; Figure 5-3). Total biomass by cove varied temporally and spatially (Figures 5-4a and 5-4b). Patterns of annual variation were similar among coves in direction but differed in magnitude. Biomass among coves within a year (spatial variation) varied greatly and showed no distinct patterns, with the exception of Little River, which had the highest biomass of all coves in the two years it was sampled.

Biomass by species was highly variable among years (Table 5-3). Percent of total biomass by species varied among coves and between years for the same coves (Figure 5-5). Bluegill sunfish were the dominant species by weight in all

years. Gizzard shad and largemouth bass were one of the top five biomass contributors every year sampled. The other top 10 IRI species that ranked in the top five biomass species were redear sunfish (3 years), spotted sucker (2 years), common carp (2 years), threadfin shad (1 year) and black crappie (1 year). Silver redhorse was the only species outside of the top 10 IRI species that ranked as one of the top five biomass contributors in any year (1 year).

Size composition was variable for some species and relatively constant for others across years (Figure 5-6). Black crappie exhibited the widest variation in size across years with the percent (by weight) of harvestable sized black crappie going from 76 percent in 1985 to 20 percent in 1994, respectively. Common carp exhibited no variation with 100 percent of all carp being harvestable size.

Information for all fish caught are summarized in Appendix C (Sections 2 and 3). Section 2 provides summaries by year in standard Surber table format. Section 3 provides catch for all species by cove and year and the weighted mean for all coves by year.

Routine and Moratorium Gill Netting (meshes 25.4 mm and larger)

The top 10 IRI species for this gear were: gizzard shad, hybrid bass, striped bass, longnose gar, common carp, silver redhorse, channel catfish, river carp-sucker, black crappie, and white perch. These ten species accounted for over 90 percent and 91 percent of the total number and weight of fish caught during the study period, respectively (Tables 5-4 and 5-5).

Spatial variability in CPUE among months

Seasonality in total catch (all species) was much more pronounced at stations 1 moratorium (1M) and 1 non-moratorium (1NM) than the other stations (Figures 5-7 and 5-8). Median CPUE's of total catch by number and weight were much higher at stations 1M and 1NM during the period of March to May than other months. Catch at 1M and 1NM were also higher than the other stations during these months. Stations 2-4 and 5 showed no obvious seasonality in CPUE by weight though median CPUE's were slightly higher in March and April, respectively. Station 5 showed a more pronounced peak in median CPUE by number in April and May. Median CV's showed slight variation among stations and months, but ranges of CV's were generally similar among stations and months. The similarity in CV's suggests that, on the average, precision of estimates is the same for all stations and months.

Several IRI species showed distinct spatial trends in CPUE among months (see Figures 5-9 thru 5-28). For hybrid bass, highest CPUE at all stations occurred in March and April. Longnose gar had essentially zero CPUE's at all stations from

December to April. Common carp catch was highest at 1M and 1NM in April and May. Silver redhorse CPUE's were essentially zero at stations 1M and 1NM from June to November. River carpsucker were rarely caught at stations 1M and 1NM in months other than April and May, and were generally not caught at other stations during summer months.

Spatial variability in CPUE among years

Mean annual catch rates for all species and the top 10 IRI species are provided in Figures 5-29 and 5-30. Because catch was highly seasonal for certain species and stations, means for years with missing samples should be evaluated carefully and the likely result of the missing samples on the calculation of the mean taken into account. For example, total catch for station 1M is probably underestimated in 1990 and 1991 because March and April, respectively, were not sampled and are typically the highest catches of the year for that station.

Mean annual total CPUE (all species) by kilograms and numbers were variable among years and between stations for the same year. Station 1NM had the two highest CPUE's by weight for the study period and was typically higher than all other stations within years. CPUE by number and weight at station 1NM decreased from 1986 to 1992 but has been fairly constant since 1992. There was an opposite trend at Station 5 where CPUE remained at relatively low levels until 1992 and then increased to higher levels until the end of the study period.

Annual catch rates for the top 10 IRI species varied greatly among years and between stations. Gizzard shad were generally most abundant at station 2-4 until 1992. In 1992, biomass and numbers of shad increased at station 5 to levels roughly equivalent to stations 2-4. Catch at 1M and 1NM were variable among years but usually relatively low. Annual catch rates of hybrid and striped bass were highest at 1NM for most years. Stations 1M, 2-4 and 6-11 were similar in range of CPUE's by weight. Mean annual CPUE of hybrid and striped bass at station 5 was relatively low for the entire study period. Longnose gar showed longitudinal patterns in distribution with CPUE being highest at the downlake stations (6-11), moderate at station 5, low at stations 2-4, and always very low at stations 1M and 1NM. CPUE by biomass of common carp was comparable among stations overall, but much more variable at stations 1M and 1NM than the other stations. CPUE of silver redhorse decreased sharply at station 1NM in 1990 and has remained low. CPUE at other stations has been fairly constant among years. Prior to 1990, CPUE of silver redhorse was much higher at station 1M than other stations. Since 1990, CPUE was highest at stations 2-4. Silver redhorse were virtually non-existent in downlake samples, with zero catches reported for two of the three years sampled. Channel catfish CPUE showed pronounced longitudinal spatial patterns in distribution. Channel catfish were virtually absent from stations 1M and 1NM, present in low abundance at stations 2-4, and relatively abundant at stations 5 and 6-11. Channel catfish CPUE's were highly variable among years at station five, but have increased steadily since 1991. River carpsucker also showed longitudinal patterns of distribution with the highest

catches in the tailwater areas. From 1986 to 1990, CPUE of river carsuckers was relatively high at stations 1M, 1NM, and 2-4, low at station 5, and close to zero at station 6-11. Since 1990, river carsucker abundance has decreased sharply at all stations. Black crappie and white perch showed similar patterns in abundance both temporally and spatially. Catch was highly variable among years at all stations. However, CPUE's of both species have increased at stations 2-4 and 5 since 1992.

Species composition

The percent of total weight represented by each species for each station and year, and all stations pooled, is presented in Figure 5-31. Temporal and spatial patterns are similar to those discussed above, but evaluate trends relative to total catch rather than tracking catch of a particular species. For example, even though catch of white perch increased three-fold (by weight) at station 5 in 1996, Figure 5-31 shows that white perch are still a minor component of the overall catch of this gear in terms of biomass. The relative importance of each species overall is best illustrated by the data pooled among stations (Figure 5-31, All stations).

Size composition

There was little variation in size composition for all IRI species (Figure 5-32) with the majority of biomass consisting of harvestable sizes. This is likely the result of gear selectivity (i.e., this evaluation is only using fish from meshes greater than or equal to 25.4 mm) for larger fish and is probably not indicative of the relative abundance of smaller size classes.

Routine and Moratorium Gill Netting (meshes less than 25.4 mm)

The top 10 IRI species for this gear were: blueback herring, threadfin shad, longnose gar, gizzard shad, white perch, hybrid bass, yellow perch, striped bass, channel catfish, and spottail shiner. These ten species accounted for over 98 percent and 97 percent of the total number and weight of fish caught during the study period, respectively (Tables 5-6 and 5-7). Three species (blueback herring, threadfin shad and longnose gar) dominated the catch and accounted for over 92 percent and 78 percent of the numbers and weight of fish collected, respectively.

Spatial variability in CPUE among months

Seasonality in total catch (all species) was much more pronounced at stations 1M and 1NM than the other stations (Figures 5-33 and 5-34). Median CPUE's of

total catch by number and weight were much higher at stations 1M and 1NM during the period of April to June than other months. Catch at 1M and 1NM were also higher than the other stations during these months. CPUE at stations 2-4 and 5 were highest during warm weather months (May thru September). Ranges of CV's were generally similar among stations and months.

Numerous IRI species showed distinct spatial trends in CPUE among months (Figures 5-35 thru 5-54). For blueback herring, CPUE's were highest at all stations in April and May and highest at stations 1M and 1NM. Threadfin shad, gizzard shad and longnose gar were only caught in warmer months with zero or low CPUE's at all stations from November to April. Catch of threadfin shad was much higher at station 1 during moratorium periods than non-moratorium periods. CPUE's of gizzard shad and longnose gar were highest at stations 2-4 and 5. Catch of yellow perch was highest from February to April at stations 1M and 1 NM, but similar among months at stations 2-4 and 5. Spottail shiner CPUE's were variable but were highest at stations 1M and 1NM from February to June. White perch, hybrid bass, striped bass, channel catfish showed no consistent seasonal trends in catch.

Spatial variability in CPUE among years

Mean annual total CPUE (all species) by kilograms and numbers were variable among years and between stations for the same year (Figures 5-55 and 5-56). Total catch was usually highest at stations 1M and 1NM within years.

Annual catch rates for the top 10 IRI species varied greatly among years and between stations. Blueback herring were generally most abundant at stations 1M and 1NM and virtually absent from station 5. Annual catch rates of threadfin shad were variable among years, but patterns of annual variation were similar across stations. Annual catch of longnose gar was highest at stations 2-4 and 5 and relatively constant from 1992 to 1996. Annual CPUE's for gizzard shad were variable with no discernable patterns. Annual abundance of white perch has increased at all stations from 1992 to 1996. Annual catch of threadfin shad, longnose gar, gizzard shad, and white perch were much lower at station 1 in non-moratorium samples than moratorium samples. Annual CPUE's for hybrid bass were variable with no discernable annual patterns, but were highest at station 1M for three of the five years. Annual CPUE's for yellow perch were highest at station 1M, similar at stations 1NM and 2-4, and low at station 5 for all years. Annual CPUE's for striped bass were variable with no discernable annual patterns. Channel catfish catch was much higher at station 5 in all years than the other stations. Spottail shiner abundance was variable among years but was generally higher at stations 1M and 1NM than the other stations.

Species composition

The percent of total weight represented by each species for each station and year, and all stations pooled, is presented in Figure 5-57. Blueback herring dominated the catch at Stations 1M and 1NM while threadfin shad and longnose gar dominated the catch at stations 2-4 and 5.

Size composition

There was slight variation in size composition among years and between stations within years for all IRI species (Figure 5-58). For example, intermediate sized fish composed the majority of the blueback herring catch (by number) in all years at all stations.

Electrofishing

The top 10 IRI species for this gear were: bluegill sunfish, largemouth bass, yellow perch, silver redhorse, spottail shiner, redear sunfish, spotted sucker, gizzard shad, threadfin shad and whitefin. These ten species accounted for over 90 percent and 80 percent of the total number and weight of fish caught during the study period, respectively (Tables 5-8 and 5-9).

Spatial variability in CPUE among months

There was no identifiable seasonality in total catch (all species) at any station, except that median CPUE's were lowest at station 5 in June and July. Median CPUE's at other stations, and other months for station 5, varied differently in numbers and weight, and ranges of mean CPUE's were highly variable within months (Figures 5-59 and 5-60). Median CV's showed slight variation among stations and months, but ranges of CV's were generally similar among stations and months.

Relatively few of the IRI species showed spatial trends in CPUE among months (Figures 5-61 thru 5-80). Yellow perch had the highest CPUE's at station 1 from January to June. CPUE's of silver redhorse were lowest at station 5 in June and July. Spottail shiner abundance was highest at station 1 from January to April and lowest at stations 2-4 and 5 from May to August and May to June, respectively).

Spatial variability in CPUE among years

Mean annual total CPUE (all species) by kilograms and numbers were highly variable among years and between stations for the same year (Figures 5-81 and

5-82). Over all years, mean total CPUE by weight tended to be highest at station 1, was similar at stations 2-4 and 5, and slightly lower at station 6-11.

Annual catch rates for the top 10 IRI species also varied among years and between stations. Bluegill sunfish and largemouth bass showed similar trends in CPUE by weight over time and space. CPUE by weight has steadily decreased at all stations since 1992. CPUE of yellow perch showed a longitudinal distribution with highest catch rates at station 1, followed by much lower CPUE's at station 2-4, and very low CPUE's at stations 5 and 6-11. CPUE's of silver redhorse were highest and approximately equal at stations 2-4 and 5. CPUE of silver redhorse at station 6-11 was very low. CPUE's of spottail shiner and redear sunfish were variable, but similar (within species) among stations. CPUE's of spotted sucker and gizzard shad showed different patterns between CPUE by number and CPUE by weight. Highest numbers of both species occurred at station 5 while the highest biomass generally occurred at station 1. This discrepancy was related to the size distributions of spotted sucker and gizzard shad at each station (see size composition section). Annual CPUE of threadfin shad was sporadic for all stations and revealed no clear spatial patterns in abundance. Lastly, abundance of whitefin shiner was highest at station 2-4.

Species composition

The percent of total weight represented by each species for each station and year, and all stations pooled, is presented in Figure 5-83. Bluegill sunfish, largemouth bass and, to a lesser extent, spotted sucker were major components of catch at all stations. Silver redhorse was a major biomass contributor at stations 2-4 and 5, but not at stations 1 or 6-11.

Size composition

Size composition was variable for most IRI species among stations and years (Figure 5-84) but general statements can be made for some species. Species which had one size group that typically contributed to the majority of the numbers for that species were: bluegill sunfish - intermediates; largemouth bass - harvestables; silver redhorse - harvestables; and redear sunfish - harvestables. Size distributions of spotted sucker and gizzard shad varied by station. All spotted suckers and gizzard shad collected at station 1 were of harvestable size. At station 5, fingerling and intermediate sizes made up a large percentage of the fish collected in most years. Size distributions of yellow perch were variable, but the presence or absence of fingerlings was similar among stations within years. Fingerling yellow perch were captured in relatively higher numbers from 1986 to 1988 and again in 1993 to 1995. Whether this phenomenon is random, related to slower growth in those years, or related to cyclic reproduction is unknown.

Horizontal "Clupeid" Gill Netting

This section presents results from the original horizontal blueback herring nets that were set from April of 1989 to February of 1992. Samples were also obtained in March and August of 1996 (concurrent with hydroacoustics sampling) but had different objectives than the previous sampling, used a different net configuration and have already been reported by Bruce and VanDenAvyle (reports attached as appendices G and H). Therefore, the 1996 data are not included in these results. For the 1989 to 1992 data, only blueback herring and threadfin shad data are summarized, but information on catch of all other species is presented in Tables 5-10 and 5-11.

Spatial variability in CPUE among months

Blueback herring CPUE's were highest at all stations in April, May and June with the highest CPUE's at stations 1 (Figures 5-85 and 5-86). CPUE's of threadfin shad were highest from May to October at all stations (Figures 5-87 and 5-88). Abundance of threadfin shad was lowest at station 1 in all months. Though lowest at station 1, peak catches approached 80 fish/net.

Spatial variability in CPUE among years

Mean annual total CPUE (both species) by kilograms and numbers were variable among years and between stations for the same year (Figures 5-89 and 5-90). Total catch was highest at station 1 within years. Blueback herring were most abundant at station 1 and virtually absent from station 5 in all years. Annual catch rates of threadfin shad were variable among years, but patterns of annual variation were similar across stations. Abundance of threadfin shad was lowest at station 1 in all years.

Species composition

The percent of total weight represented by each species for each station and year, and all stations pooled, is presented in Figure 5-91. Blueback herring dominated the catch at station 1 while threadfin shad dominated the catch at stations 2-4, 5, and 6-11. Across the lake as a whole (All Stations), blueback herring biomass increased steadily from 1989 to 1992 relative to threadfin shad biomass.

Size composition

There was slight variation in size composition among years and between stations within years for either species (Figure 5-92). Intermediate sized fish

composed the majority of the catch (by number) for both species in all years and at all stations.

Ichthyoplankton Sampling

The following results are paraphrased from VanDenAvyle (1990) and Zimpfer (1990). Additional references (attached as appendices E and F) relating to larval fishes in J. Strom Thurmond are Higginbotham (1991) and Betsill (1996).

Four major taxa made up more than 98 percent of the larvae collected at all sites. The four taxa were clupeids (threadfin shad, gizzard shad, and blueback herring), crappies (white crappie and black crappie), sunfish (bluegill, redbreast, redear, and several others), and yellow perch. Species composition was similar among regions of the lake. Larval fish densities were lowest at tailwater stations (1-3) and highest at tributary stations (4, 5, 6, and 11).

Spawning peaks varied by up to a month annually, but relative timing for the four major taxa was the same. Yellow perch were the earliest spawners, followed by crappies, clupeids and sunfish. The timing of spawning was similar among regions of the reservoir within each year.

For samples in the immediate area of the dam, larval fish abundance was very low in the Richard B Russell forebay and at station 1. This finding suggested that few larvae were entering JST from RBR. Abundance of larvae in the tailwaters generally increased with distance from the RBR Dam. Lastly, diel studies at station 2 revealed that densities of larval fish were always low during or immediately after generation.

Zooplankton Sampling

The following results are paraphrased from Betsill (1996). An additional reference relating to zooplankton and larval feeding in J. Strom Thurmond is Higginbotham (1991).

Rotifers (14 genera) averaged more than 70 percent of total zooplankton collected each year. The seasonal progression in relative abundance of rotifer genera was *Polyarthra* (February to May) to *Keratella* (June) to a variety of small rotifers consisting of *Conochilus*, *Pleosoma*, *Conochiloides* and *Branchionus* (July). Crustacean zooplankton made up a small proportion of total zooplankton and only copepod nauplii regularly exceeded 10 percent.

Significant differences in abundance of rotifers were found between uplake and downlake areas on 15 of 17 dates. Differences in zooplankton abundance were also found between mainlake sites and embayments but were ephemeral in nature.

Spring peaks in zooplankton abundance occurred later at upstream sites than at downstream sites.

Telemetry

The following results are paraphrased from Welch (1990). Additional references (attached) relating to radio tracking of hybrid bass and sauger in J. Strom Thurmond are Windham (1986) and Earle (1991), respectively.

Hybrid and striped bass were widely distributed in the upper portion of the reservoir during spring months (March to May). However, movements of fish from June to September were limited to certain locations along the upper Savannah arm of the reservoir. Sauger movements were restricted to the tailwater area throughout the spring and summer of both years.

Conventional operation of RBR Dam had little influence on the movements of hybrid bass or sauger. In addition, there were no movements toward or away from the dam in response to generation.

Other Sampling Methods

Vertical gillnetting showed distinctly different behavioral distributions of blueback herring and threadfin shad during stratified periods of the year (July, August, and September). Blueback herring occurred at depths of 4-14 meters where temperatures ranged from 17-24 °C (Figure 5-93). Threadfin shad occurred primarily in the upper two meters of the water column at temperatures of 24-29 °C. Temperature was an important factor in distribution of bluebacks as approximately 30 percent of blueback herring were found at temperatures where dissolved oxygen levels were below 5 ppm.

Blueback herring appeared to move uplake as stratification became more pronounced (Figure 5-94). Catch of bluebacks was highest at downlake stations (9 and 10) in May and June but higher at stations 7 and 8 in July August and September. Blueback herring were rarely caught at any time up the Little River arm in Georgia (station 11). Surprisingly, catch of threadfin shad was also lower downlake from July to September. Threadfin appeared to move up both the Savannah and Little River arms during the summer as catch increased at stations 7, 8 and 11 during this time.

Purse seine samples at station 1 caught few fishes other than blueback herring and threadfin shad (Table 5-24). Blueback herring were usually the dominant species and often comprised 100 percent of the catch for a given month (Figure 5-95). Catch of threadfin shad was sporadic among months as with the other gears previously reported. Length frequency distributions of blueback herring were similar within months across years (1988 and 1989). Two modes of bluebacks were

typically evident from March to June. Modes in March were the 120 and 160 mm groups. The 120 mm mode progressed to 160 to 170 mm groups by October. The larger mode was not as easily discerned over time and appeared to broaden over time. A smaller mode (70 mm) was evident only in September 1989. This is also the time of year that this size of blueback herring was recruited into the catch of small meshed gillnets. The infrequency of capture and generally low numbers of threadfin shad prohibit even general conclusions regarding size distributions over time.

Relatively few fish were collected in any of the draft tube dewatering samples taken from 1988 to 1994 (Table 5-25). The mean numbers and weights (in grams) of fish for all samples were 13 and 543 (or 0.543 kilograms), respectively. The highest number of fish collected in any sample was 44 fish in February 1988. Forty-one of these were threadfin shad. The highest biomass of fish collected in any sample was approximately 2 kilograms in November 1988. Over 90 percent of the biomass of this sample consisted of flathead catfish. Five ictalurid species were collected and ictalurids often comprised the majority of biomass for all samples. As with other gears, white perch did not appear in samples until 1991 and was present in all, but one, subsequent samples.

Richard B. Russell Reservoir

Rotenone sampling

The top 10 IRI species for this gear were: threadfin shad, bluegill sunfish, common carp, gizzard shad, yellow perch, redbreast sunfish, largemouth bass, green sunfish, redear sunfish, and warmouth sunfish. These ten species accounted for over 98 percent by number and 94 percent by weight of all fish caught during the five years evaluated (Tables 5-12 and 5-13). The top 10 IRI species accounted for 94 percent, 94 percent, 88 percent, 98 percent, 95 percent, 89 percent and 91 percent of the total biomass sampled from 1990 to 1996, respectively (Tables 5-14).

Total fish biomass varied considerably across the five years (range 48 to 186 kg/ha; Table 5-14, Figure 5-96). Total biomass by cove varied temporally and spatially (Figures 5-97a and 5-97b). Patterns of annual variation were generally similar among coves in direction but differed in magnitude. Total kilograms/hectare was highest for all coves in 1994. Within years (spatial variation), Dam cove had the lowest biomass estimate every year except for 1991. Island and Elbert coves varied in relation to each other, but were generally similar.

Biomass by species was highly variable among years (Table 5-14). Percent of total biomass by species varied among coves and between years for the same coves (Figure 5-98). Common carp were the dominant species by weight in all years except 1996. Gizzard shad, bluegill, and threadfin shad were one of the top five biomass contributors every year sampled. The other top 10 IRI species that ranked as one of the top five biomass contributors were largemouth bass (3 years)

and yellow perch (1 year). Three species outside of the top 10 IRI species ranked as one of the top five biomass contributors in any year. They were chain pickerel (5th in 1990; 1.76 kg/ha), channel catfish (5th in 1992; 2.39 kg/ha) and black crappie (4th in 1996; 2.2 kg/ha).

Size composition was variable for some species and relatively constant for others across years (Figure 5-99). Relative abundance of fingerlings was highest in 1993 and 1994 for many of the littoral species (yellow perch, redbreast sunfish, green sunfish, and warmouth sunfish). With the exception of redbreast sunfish, the higher relative abundance of fingerlings appears to be due to higher reproduction in 1993 and 1994 as these were also the years with the highest biomass of fingerlings. For redbreast sunfish, the increase in the percent of fingerlings was not related to higher reproduction as the biomass of fingerlings in 1993 and 1994 was not appreciably higher than other years (and was lower than some years).

Information for all fish caught are summarized in Appendix C (Sections 4 and 5). Section 4 provides summaries by year in standard Surber table format. Section 5 provides catch for all species by cove and year and the weighted mean for all coves by year.

Routine Gill Netting (meshes 25.4 mm and larger)

The top 10 IRI species for this gear were: gizzard shad, common carp, long-nose gar, largemouth bass, white perch, channel catfish, black crappie, hybrid bass, silver redhorse, and white catfish. These ten species accounted for over 91 percent and 91 percent of the total number and weight of fish caught during the study period, respectively (Tables 5-13 and 5-14).

Spatial variability in CPUE among months

Total catch (all species) varied by month and between stations within months (Figures 5-100 and 5-101). Median catch rates were higher at stations 21-23 and 24 in May, but ranges in CPUE were similar among months. CPUE's of all species pooled were variable at station 25, and similar in range, among months.

Because sampling was restricted to "warm weather" months (May through October) each year, seasonal or monthly trends in catch were difficult to discern or were not apparent for most IRI species (Figures 5-102 thru 5-121).

Spatial variability in CPUE among years

Mean annual total CPUE (all species) by kilograms and numbers was variable among years and between stations for the same year (Figures 5-122 and 5-123). However, total catch in numbers and weight were of similar magnitude with the

exception of station 24 in 1990 and 1991 which was much lower than the other stations.

Annual catch rates for the top 10 IRI species also varied among years and between stations. Annual CPUE's of gizzard shad were similar among stations in magnitude with the exception of station 24 in 1990 and 1991. Abundance of carp was highest at station 25 in all years sampled, and similar among stations 21-23 and 24. Longnose gar were generally least abundant at station 24 and similar at stations 21-23 and 25. CPUE by weight of largemouth bass was nearly identical in magnitude and in year to year fluctuations at stations 21-23 and station 25. CPUE of largemouth bass was always relatively low at station 24. White perch were rarely caught at any station other than station 25 and annual catch at station 25 was highly variable. CPUE's of channel catfish by weight generally increased at all stations over the seven years sampled. Abundance of channel catfish was lower at stations 21-23 than the other stations. Hybrid bass were most abundant at station 21-23 in all years and rarely sampled at the other stations. CPUE's silver redhorse were highest at station 21-23, and low or zero at stations 24 and 25. Lastly, CPUE's of white catfish were generally similar at all stations among years.

Species composition

Temporal and spatial patterns in species composition are similar to those discussed above. For the lake as a whole (all stations), gizzard shad, common carp, and longnose gar made up over 50 percent of the total biomass in all years sampled (Figure 5-124). These three species also constituted a large portion of the biomass at each station. The other top ten IRI species that generally contributed at least 10 percent to the total biomass at a station were channel catfish and black crappie station 24, and hybrid bass at station 21-23.

Size composition

There was little variation in size composition for all IRI species (Figure 5-125) with the majority of biomass consisting of harvestable sizes. This is likely the result of gear selectivity (i.e., evaluation only using fish from meshes greater than or equal to 25.4 mm) for larger fish and is probably not indicative of the relative abundance of smaller size classes.

Routine Gill Netting (meshes less than 25.4 mm)

The top 10 IRI species for this gear were: threadfin shad, blueback herring, longnose gar, common carp, bluegill sunfish, gizzard shad, spottail shiner, whitefin shiner, white perch and yellow perch. These ten species accounted for over 99 percent and 93 percent of the total number and weight of fish caught during the study period, respectively (Tables 5-17 and 5-18). Three species (blueback

herring, threadfin shad and longnose gar) dominated the catch and accounted for over 95 percent and 78 percent of the numbers and weight of fish collected, respectively.

Spatial variability in CPUE among months

CPUE by weight of all species pooled was highly variable with no consistent trends among stations or months (Figure 5-126). CPUE by number of all species pooled was generally much higher in May than other months at all stations (Figure 5-127).

Several IRI species showed distinct trends in CPUE among months (Figures 5-128 thru 5-147). CPUE's of threadfin shad and blueback herring were highest in May at all stations, but were variable in May among stations. Longnose gar and common carp showed no distinct monthly patterns in CPUE but both species were caught more frequently at stations 21-23 and 25 than at station 24. Bluegill sunfish and gizzard shad showed no monthly trends in CPUE. CPUE's of spottail and whitefin shiners were highest from May to June at all stations and similar among stations. White perch and yellow perch were caught sporadically at all stations. Bluegill sunfish and gizzard shad showed no monthly trends.

Spatial variability in CPUE among years

Mean annual total CPUE (all species) by kilograms and numbers was variable among years and between stations for the same year (Figures 5-148 and 5-149). Total catch by weight was generally highest at station 25 which also exhibited the greatest year to year variation. Total catch by number (which was essentially the catch threadfin shad) showed no distinct annual patterns among stations.

Annual catch rates for the top 10 IRI species also varied greatly among years and between stations within years. In fact, few generalizations can be made from this gear. Common carp were generally absent from samples at station 24 with zero catch rates in four of the five years. Gizzard shad were most abundant at station 24 with very low catches at stations 21-23 and 25.

Species composition

Temporal and spatial patterns in species composition are similar to those discussed above. For the lake as a whole (all stations), longnose gar averaged over 50 percent of the total biomass for all years sampled (Figure 5-150). Longnose gar were the dominant biomass species at stations 21-23 and 25 in all years, and was variable at station 24. Threadfin shad and blueback herring made up the largest portion of the remaining biomass at all stations in most years. Common carp were sporadically important at all stations and gizzard shad contributed to total biomass only at station 24.

Size composition

There was some variation in size composition for most IRI species (Figure 5-151), but overall (all stations) the majority of the biomass within species generally consisted of a specific size, or the relative percentages of sizes were similar. The one exception was blueback herring which steadily went from consisting of mostly harvestable sizes to consisting of mostly intermediate sizes.

Electrofishing

The top 10 IRI species for this gear were: bluegill sunfish, largemouth bass, threadfin shad, redbreast sunfish, green sunfish, yellow perch, yellow bullhead, spottail shiner, common carp and redear sunfish. These ten species accounted for over 97 percent and 84 percent of the total number and weight of fish caught during the study period, respectively (Tables 5-19 and 5-20).

Spatial variability in CPUE among months

Total catch (all species) varied among months and stations within months, but the highest catches within a year at all stations usually occurred in May or October (Figures 5-152 and 5-153).

Few IRI species showed spatial trends in CPUE among months or monthly trends among years (Figures 5-154 through 5-173). Bluegill sunfish were one of the few exceptions with highest CPUE's typically in May or October, and monthly patterns within years were similar among stations. Largemouth bass CPUE's were also highest in May or October but there were no consistent trends among stations within years or years within stations. CPUE's of largemouth bass were higher at station 24 for most given months and years. There were no discernable monthly patterns in threadfin shad CPUE's, but catch was generally higher at station 24 with threadfin shad being caught infrequently at the other stations. CPUE's for the other top 10 IRI species were highly variable among stations within months and did not show any monthly patterns across years.

Spatial variability in CPUE among years

Mean annual catch rates for all species and the top 10 IRI species are provided in Figures 5-174 and 5-175. Mean annual total CPUE (all species) by kilograms and numbers were highly variable among years and between stations for the same year. Over all years, mean CPUE was higher at station 24 than stations 21-23 or 25.

Annual catch rates for the top 10 IRI species were highly variable among years and between stations. CPUE's of bluegill sunfish, largemouth bass and threadfin shad were higher at station 24 in almost all years than the other stations.

Redbreast sunfish have generally decreased in numbers at all stations since 1992 while green sunfish numbers increased since 1994. None of the other IRI species showed definable trends in annual abundance.

Species composition

Bluegill sunfish and largemouth bass constituted the majority of the biomass at all stations in virtually all years (Figure 5-176). Common carp were the only other IRI species that frequently contributed more than 10 percent to the total biomass at all three stations.

Size composition

Relative proportions of size classes by number were variable for some species and relatively constant for others. Size composition of bluegill sunfish, largemouth bass, threadfin shad, redbreast sunfish and common carp were relatively constant across years overall (Figure 5-177; all stations).

Horizontal "Clupeid" Gill Netting

Though only blueback herring and threadfin shad data are summarized below, information on catch of all other species is presented in Tables 5-21 and 5-22. Because this gear was only used for one year, conclusions regarding spatial or temporal patterns in abundance were limited. However, the distribution of catch by month for these two species was similar to that from the routine gillnets (meshes less than 25.4 mm) in following years.

Spatial variability in CPUE among months

Blueback herring catch was highest at all stations in May and was sporadic in other months. Blueback herring CPUE's were highest at station 21-23 (Figure 5-178 and 5-179). CPUE's of threadfin shad were highest in May at stations 21-23 and 25, and in October at station 24 (Figures 5-180 and 5-181). Threadfin shad were caught infrequently (for threadfin shad) at all stations, with the highest catch for any month or station being approximately four fish/net.

Spatial variability in CPUE among years

No data for this gear (see routine gillnetting- meshes less than 25.4 mm).

Species composition

For the catch of blueback herring and threadfin shad, blueback herring constituted 97 percent of the catch by weight across all stations (Figure 5-182).

Size composition

Blueback herring catch consisted mostly of intermediate sizes (68 percent for all stations) with the remainder of catch being harvestable sizes (Figure 5-183). Threadfin shad catch consisted of almost entirely of intermediate sizes.

Discussion

One of the goals of baseline sampling was to define temporal patterns in abundance of fishes at station 1 (immediate tailrace) for predicting potential entrainment during pumpback operation of the dam. Predictions regarding potential entrainment depend on the parameter of interest (i.e., numbers or biomass). When numbers only are evaluated, predictions will be based essentially on threadfin shad and blueback herring, as these two species totally overwhelmed all other species in terms of numbers/net during peak catch times. However, threadfin shad are essentially unimportant and blueback herring less important in determining temporal distribution of biomass.

The culmination of baseline sampling efforts (Table 5-23) shows that the highest biomass of fish occurs at station 1 during the period of March, April and May. In fact, this period encompassed all species that showed definable temporal trends in distribution. Numbers of all fish other than threadfin shad were also highest during these months. Peaks in threadfin shad abundance ranged from March to September for all gears, and numbers/net (or transect) were often very high. The "boom or bust" nature of threadfin shad catches suggests that potential entrainment (by number) could be very high in any month between March and September. It is important to note that temporal predictions in entrainment are *relative* and do not imply that entrainment in other months will necessarily be low in terms of absolute numbers or biomass. Absolute numbers cannot be inferred from catch rate data.

Use of the top ten IRI species was a good way to represent the majority of the data, even for gears that collected the highest diversity of species. The top 10 IRI species typically accounted for over 90 percent by number and 80 percent by weight of total catch for a given gear and exceeded 95 percent by number and weight for some gears. The lower percentage by weight usually resulted from a few (in relative terms) large individuals from a few infrequently caught species. Because the IRI scores were calculated for all years and stations pooled, there were a few cases where a relatively large percentage of total biomass for a given station or year was from an unknown species. However, Tables 5-1 through 5-22

provide a general idea of the non-IRI species that likely provided substantial biomass to catch.

Defining long-term trends in abundance is important for future evaluations of the effects of pumpback operation on the respective fisheries. For example, extirpation of a species after pumpback operations may not be related to pumpback if the species showed continual declines in abundance prior to 1996. There were several long term trends identified for JST fishes. Abundances of black crappie and white perch have increased in JST over the eleven years of study based on routine gillnetting. These increases were also evident in cove rotenone sampling (Sections 3 & 4 in Appendix C). White perch were not captured in rotenone samples until 1990, and increased from 5 fish/ha (0.11 kg/ha) in 1990 to 148 fish/ha (2.66 kg/ha) in 1994. Numbers and kilograms per hectare of black crappie were higher in 1994 than any previous year. Increased presence of white perch was also noted in draft tube dewatering samples. Sauger and walleye decreased in abundance from 1986 to 1991 and have been virtually absent from samples since. Two sauger and one walleye have been collected since 1991. Total numbers of sauger collected from 1986 to 1988 were 130, 36 and 26. Total numbers of walleye captured for the same years were 8, 10, and 5. Because almost all sauger and walleye were collected at stations 1 through 4, differences in annual numbers are not related to increased effort at stations 6-11 for those years. Lastly, river carp-sucker abundance decreased in the early 1990's and has remained low through the end of the study period.

Because of individual gear biases, a variety of gears were used during baseline monitoring to assess spatial and temporal patterns in relative abundance. Regardless of the gear, all of the results presented assume that catch rate was related to abundance in a localized area (i.e., stations) at all times. While this assumption is likely valid for most species and times of year, it should be noted that there are few species which may exhibit seasonal behavior patterns that would alter the relationship between abundance and catch. For example, because gillnetting is a passive collection gear, catch rates are dependent on the activity levels of the fish. Therefore, catch rates of a species like threadfin shad, which are lethargic at cold water temperatures, could be very low regardless of local relative abundance during cold weather months. Even active collection gears like electrofishing may be influenced by seasonal behavior patterns of fish. Some littoral species may move to slightly deeper water in colder months (and thus would not be captured by electrofishing) but stay in the same general area. These cautionary statements do not negate the results presented above, but rather, illustrate the importance of meshing these results with other gears such as hydroacoustic sampling (which is less affected by fish behavior).

Whitefin Shiner	3	5	0
Spotted Bass	2	3	0
Warmouth Sunfish	3	3	0
Silver Redhorse	1	1	1
Coosa Bass	1	2	0
Spotfin Shiner	2	2	0
Black Bullhead	1	1	0
Redbreast Sunfish	1	1	0

Table 5-23. General conclusions regarding the temporal variation in abundance of selected species at station 1 in J Strom Thurmond Reservoir.

Species	Collection Method		
	Gillnetting (meshes=>25.4 mm)	Gillnetting (meshes<25.4 mm and BBH nets)	Electrofishing
Black Crappie	Sporadic catch, generally low abundance, but highest catch rate for study occurred at Sta 1 in March 1996	Peak catch from April - June	Always present, peak catch sporadic. Catch decreased in 1995 and 1996.
Blueback Herring			
Bluegill Sunfish			
Channel Catfish			
Common Carp	Rarely caught in any month	Rarely caught in any month	
Gizzard Shad	Peak catch in April & May		
Hybrid Bass	Frequently caught but in low abundance. Peak catch sporadic		
Largemouth Bass	Peak catch in March & April	Sporadic catch	Always present, peak catch sporadic.
Longnose Gar			
Redear Sunfish	Sporadic catch	Sporadic catch	Always present, peak catch sporadic
River Carpsucker	Peak catch in April & May. Catch decreased to very low levels since 1992.		
Silver Redhorse	Peak catch in April & May. Catch decreased to very low levels since 1991.		Rarely caught in any month
Spotted Sucker			
Spottail Shiner			Always present, peak catch sporadic
Striped Bass	Always present, peak catch sporadic.	Peak catch February - June Sporadic catch	Peak catch February - May

Table 5-23. Continued

Species	Collection Method		
	Gillnetting (meshes=>25.4 mm)	Gillnetting (meshes<25.4 mm and BBH nets)	Electrofishing
Threadfin Shad			
Whitefin Shiner			
White Perch	Peak catch April - May. Catch increased since 1992.	Sporadic catch, but high numbers when caught (negligible biomass) Peak catch April & May. Catch increased since 1994.	Sporadic catch, but high numbers when caught (negligible biomass)
Yellow Perch		Peak catch February - April. Catch increased in 1995 and 1996.	Sporadic catch, generally low abundance Peak catch February - April. Catch decreased in 1995 and 1996.

Figure 5-2. Map of Richard B Russell Reservoir showing the midpoints of sampling stations 21 thru 25 and cove rotenone sampling locations.

Figure 5-3. The weighted mean kilograms per hectare for the top ten IRI species and all other species combined by year from JST rotenone sampling.

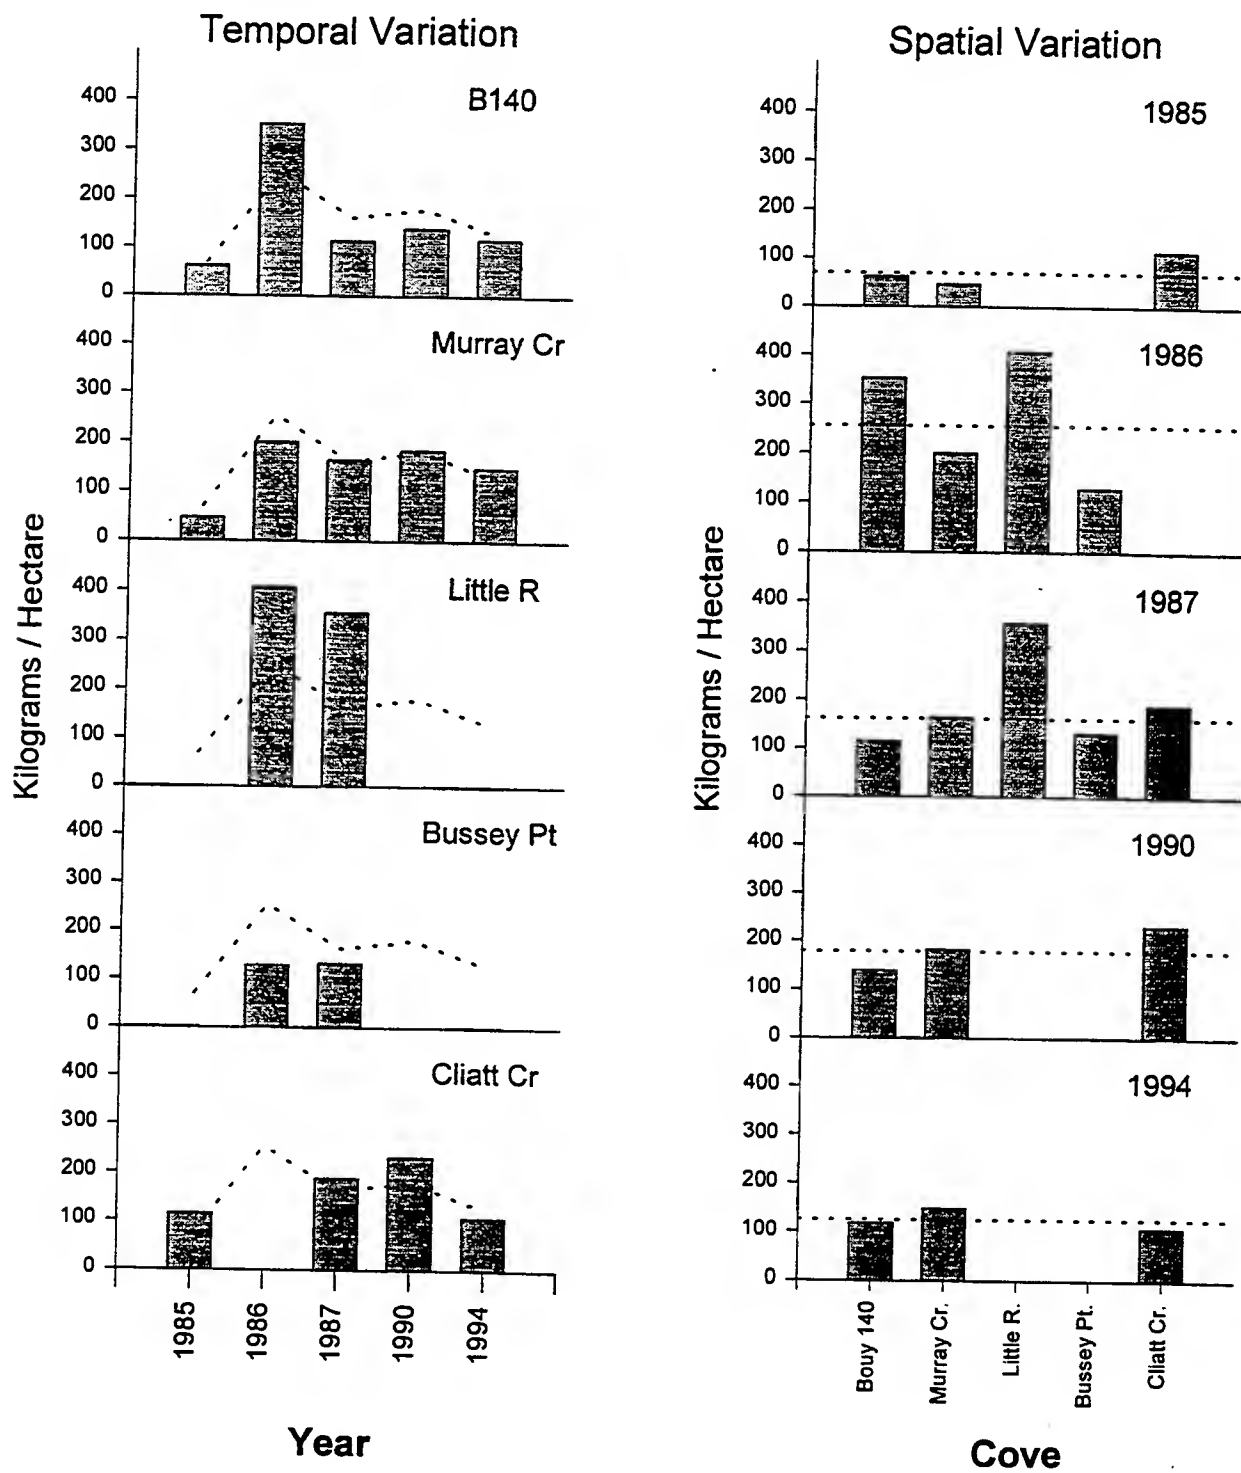

Figure 5-4. Variation in total kilograms per hectare (a) across years by cove and (b) across coves by year from JST rotenone sampling. The dotted line represents the weighted mean across all coves for each year.

Figure 5-5. Variation in the percent of total biomass for the top ten IRI species by cove and year for JST rotenone sampling.

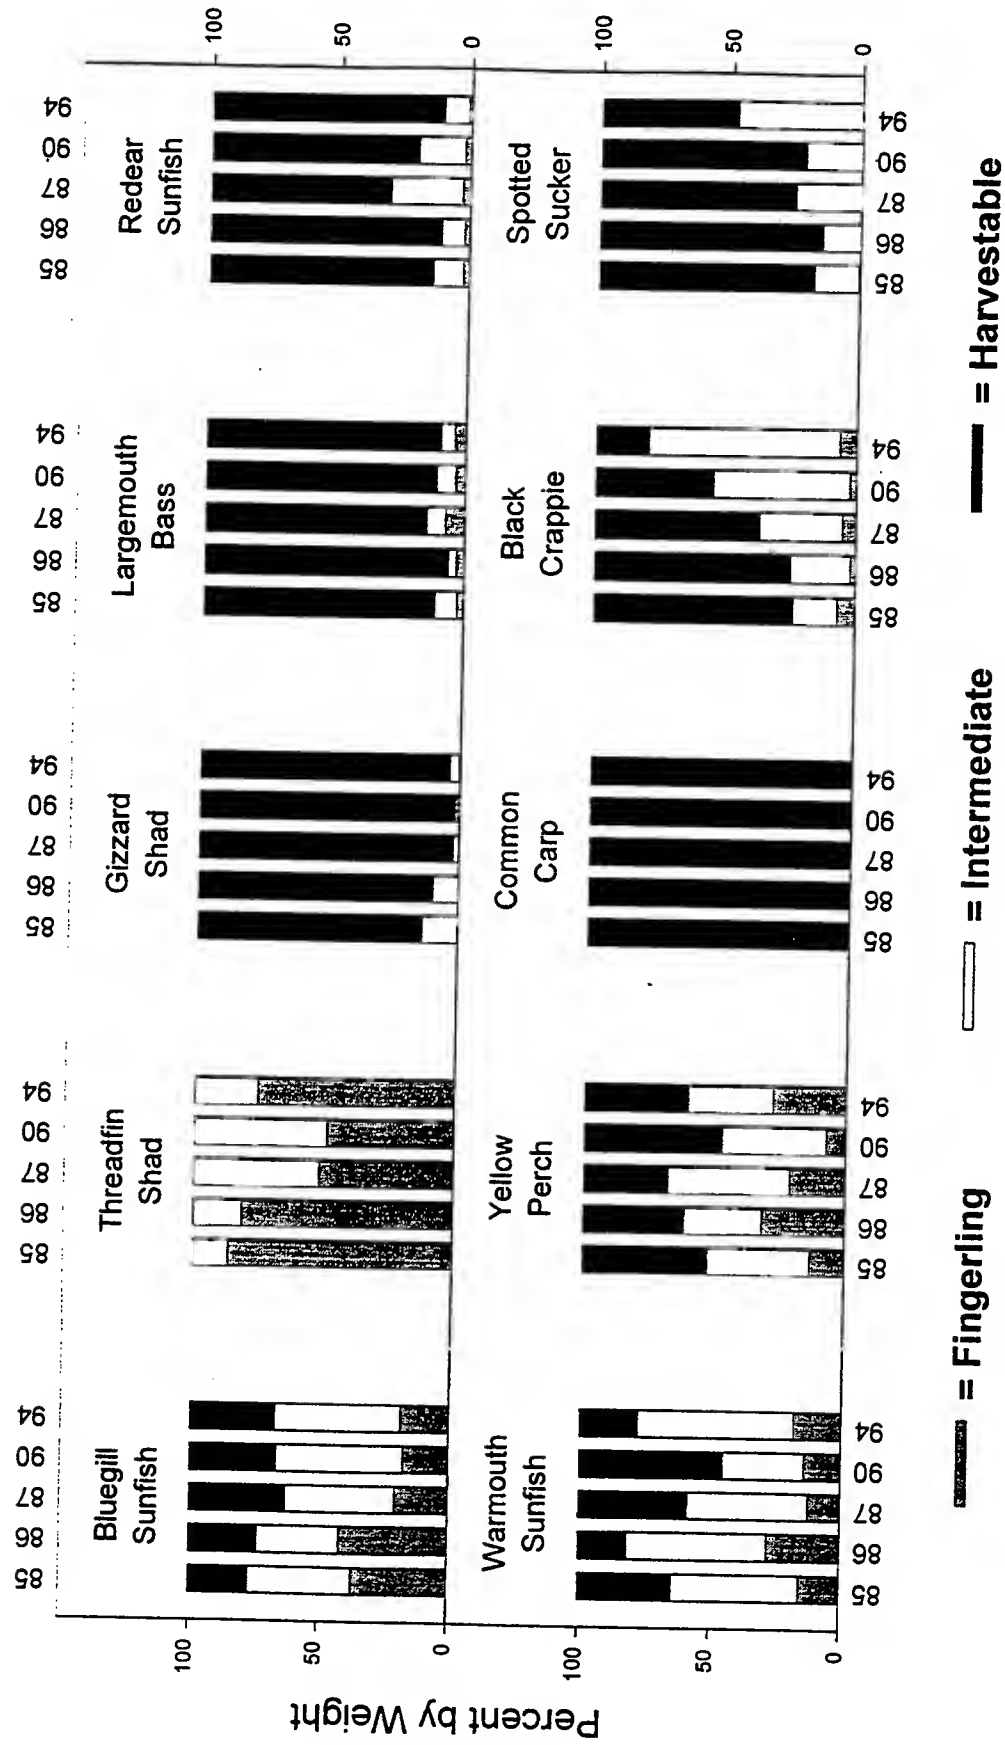

Figure 5-6. Size composition (by weight) of fingerlings (gray portion of bar), intermediates (white portion of bar), and harvestables (black portion of bar) for the top ten IRI species from JST rotenone sampling.

All Species

Routine Nets (Meshes 1" and larger)

Figure 5-7. Mean catch rate (kilograms/net) of all species pooled for JST routine and moratorium gillnetting (meshes 25.4 mm and larger). An asterisk indicates that no sampling was conducted for that month.

All Species

Routine Nets (Meshes 1" and larger)

Gizzard Shad

Routine Nets (Meshes 1" and larger)

Figure 5-9. Mean catch rate (kilograms/net) of gizzard shad for JST routine and moratorium gillnetting (meshes 25.4 mm and larger). An asterisk indicates that no sampling was conducted for that month.

Gizzard Shad

Routine Nets (Meshes 1" and larger)

Figure 5-10. Mean catch rate (numbers/net) of gizzard shad for JST routine and moratorium gillnetting (meshes 25.4 mm and larger). An asterisk indicates that no sampling was conducted for that month.

Hybrid Bass

Routine Nets (Meshes 1" and larger)

Figure 5-11. Mean catch rate (kilograms/net) of hybrid bass for JST routine and moratorium gillnetting (meshes 25.4 mm and larger). An asterisk indicates that no sampling was conducted for that month.

Hybrid Bass

Routine Nets (Meshes 1" and larger)

Figure 5-12. Mean catch rate (number/net) of hybrid bass for JST routine and moratorium gillnetting (meshes 25.4 mm and larger). An asterisk indicates that no sampling was conducted for that month.

Striped Bass

Routine Nets (Meshes 1" and larger)

Figure 5-13. Mean catch rate (kilograms/net) of striped bass for JST routine and moratorium gillnetting (meshes 25.4 mm and larger). An asterisk indicates that no sampling was conducted for that month.

Striped Bass

Routine Nets (Meshes 1" and larger)

Figure 5-14. Mean catch rate (numbers/net) of striped bass for JST routine and moratorium gillnetting (meshes 25.4 mm and larger). An asterisk indicates that no sampling was conducted for that month.

Longnose Gar

Routine Nets (Meshes 1" and larger)

Figure 5-15. Mean catch rate (kilograms/net) of longnose gar for JST routine and moratorium gillnetting (meshes 25.4 mm and larger). An asterisk indicates that no sampling was conducted for that month.

Longnose Gar

Routine Nets (Meshes 1" and larger)

Figure 5-16. Mean catch rate (number/net) of longnose gar for JST routine and moratorium gillnetting (meshes 25.4 mm and larger). An asterisk indicates that no sampling was conducted for that month.

Common Carp

Routine Nets (Meshes 1" and larger)

Figure 5-17. Mean catch rate (kilograms/net) of common carp for JST routine and moratorium gillnetting (meshes 25.4 mm and larger). An asterisk indicates that no sampling was conducted for that month.

Common Carp

Routine Nets (Meshes 1" and larger)

Figure 5-18. Mean catch rate (numbers/net) of common carp for JST routine and moratorium gillnetting (meshes 25.4 mm and larger). An asterisk indicates that no sampling was conducted for that month.

Silver Redhorse

Routine Nets (Meshes 1" and larger)

Figure 5-19. Mean catch rate (kilograms/net) of silver redhorse for JST routine and moratorium gillnetting (meshes 25.4 mm and larger). An asterisk indicates that no sampling was conducted for that month.

Silver Redhorse

Routine Nets (Meshes 1" and larger)

Figure 5-20. Mean catch rate (number/net) of silver redhorse for JST routine and moratorium gillnetting (meshes 25.4 mm and larger). An asterisk indicates that no sampling was conducted for that month.

Channel Catfish

Routine Nets (Meshes 1" and larger)

Figure 5-21. Mean catch rate (kilograms/net) of channel catfish for JST routine and moratorium gillnetting (meshes 25.4 mm and larger). An asterisk indicates that no sampling was conducted for that month.

Channel Catfish

Routine Nets (Meshes 1" and larger)

Figure 5-22. Mean catch rate (numbers/net) of channel catfish for JST routine and moratorium gillnetting (meshes 25.4 mm and larger). An asterisk indicates that no sampling was conducted for that month.

River Carpsucker

Routine Nets (Meshes 1" and larger)

Figure 5-23. Mean catch rate (kilograms/net) of river carpsucker for JST routine and moratorium gillnetting (meshes 25.4 mm and larger). An asterisk indicates that no sampling was conducted for that month.

River Carpsucker

Routine Nets (Meshes 1" and larger)

Figure 5-24. Mean catch rate (numbers/net) of river carpsucker for JST routine and moratorium gillnetting (meshes 25.4 mm and larger). An asterisk indicates that no sampling was conducted for that month.

Black Crappie

Routine Nets (Meshes 1" and larger)

Figure 5-25. Mean catch rate (kilograms/net) of black crappie for JST routine and moratorium gillnetting (meshes 25.4 mm and larger). An asterisk indicates that no sampling was conducted for that month.

Black Crappie

Routine Nets (Meshes 1" and larger)

Figure 5-26. Mean catch rate (number/net) of black crappie for JST routine and moratorium gillnetting (meshes 25.4 mm and larger). An asterisk indicates that no sampling was conducted for that month.

White Perch

Routine Nets (Meshes 1" and larger)

Figure 5-27. Mean catch rate (kilograms/net) of white perch for JST routine and moratorium gillnetting (meshes 25.4 mm and larger). An asterisk indicates that no sampling was conducted for that month.

White Perch

Routine Nets (Meshes 1" and larger)

Figure 5-28. Mean catch rate (numbers/net) of white perch for IST routine and moratorium gillnetting (meshes 25.4 mm and larger). An asterisk indicates that no sampling was conducted for that month.

Gizzard Shad Electrofishing

Figure 5-76. Mean catch rate (numbers/transect) of gizzard shad for JST electrofishing. An asterisk indicates that no sampling was conducted for that month.

Threadfin Shad Electrofishing

Figure 5-77. Mean catch rate (kilograms/transect) of threadfin shad for JST electrofishing. An asterisk indicates that no sampling was conducted for that month.

Threadfin Shad Electrofishing

Figure 5-78. Mean catch rate (numbers/transect) of threadfin shad for JST electrofishing. An asterisk indicates that no sampling was conducted for that month.

Figure 1 consists of eight panels arranged in a 4x2 grid. The rows represent four stations: Sta 1, Sta 2-4, Sta 5, and Sta 6-11. The columns represent two different metrics: Mean Catch Rate (kg/transect) and CV's (%). The x-axis for all panels is time, with years 1986-1996 and months J, F, M, A, M, J, J, A, S, O, N, D. The y-axis for the top row (Mean Catch Rate) ranges from 0.00 to 0.15 kg/transect. The y-axis for the bottom row (CV's (%)) ranges from 0 to 300%. The top row shows mean catch rates with error bars representing standard error. The bottom row shows CVs with error bars representing standard error. Sta 1 shows a significant peak in 1993. Sta 2-4 shows a significant peak in 1991. Sta 5 shows a significant peak in 1990. Sta 6-11 shows a significant peak in 1989.

6 Fixed-Aspect Hydroacoustics Studies

Summary

Full or partial recovery netting can be used to estimate entrainment through only one or two units during pumpback operation and one unit during conventional generation. Logistical and safety considerations prohibit recovery netting of all units during hydropower operation. Fixed-aspect hydroacoustics sampling is routinely used at hydropower projects to estimate fish entrainment and fish passage characteristics (e.g., timing of passage and depth distribution of entrained fish). The entrainment estimates for the net and hydroacoustic systems should be compared to ensure both are accurately sampling fish passage.

A fixed-aspect hydroacoustics system was used to monitor fish entrainment on all intake bays during pumpback operations at the Richard B. Russell Dam during the Phase III study period. During the Phase III study period the hydroacoustic system sampled five times more unit hours of pumpback operation than the nets, and provided information about fish entrainment unattainable with net sampling. Study objectives for fixed-aspect hydroacoustics sampling during Phase III pumpback operations were; (1) determine if hydroacoustics could be used to monitor entrainment rates, (2) measure entrainment through time, among intakes, and depths sampled, and (3) determine whether the entrainment rate changed with the number of units operating.

Results relating pumpback net entrainment rates to hydroacoustics entrainment rates reveal that hydroacoustics can be used to predict monthly entrainment rates. The predictive equations developed were based on both Phase II and III data because the differences in entrainment rates, species of fish entrained, fish sizes, and fish depths over the two study periods differed, and either study period alone would not adequately predict entrainment.

Entrainment associated with pumpback operations varied during the Phase III study period. The highest entrainment events predicted with hydroacoustics occurred in July, August and early September when threadfin shad were numerically dominant in the net catches. During this same period the fish counted with

hydroacoustics tended to be more surface oriented than other months, and the mean fish size entrained dropped from 6.5 inches to 4 inches. The number of units pumping during a pump event was related to the hydroacoustic entrainment rate during Phase III testing. Comparisons between 1, 2, 3 and 4 unit pump events found entrainment rates were similar when 2, 3, or all 4 units were pumping, but entrainment rates were nearly twice as high when multiple units pumped than when any single unit pumped.

Entrainment rates during Phase III pumpback operations were also compared between pump events that were preceded by conventional generation within a 24-hour period (pregeneration pumps), and pump events that were not directly preceded by conventional generation (non-pregeneration pumps). Entrainment rates for all pumpback units were higher during non pre-generation than pregeneration unit pump events except during the month of June. Although non-pregeneration unit events comprised only 11 percent of the total pump events during the period of highest entrainment (July-August 1996) during Phase III, 67 percent of the events with entrainment rates greater than 10,000 fish/hour were non pre-generation pumps.

A significant regression was not obtained between paired fixed-aspect hydroacoustics and net samples collected during conventional generation operations prior to Phase III operation. Additional sampling conducted during mid-June 1996 to determine directionality of fish in front of Unit 4 showed that two to twenty-five percent of the fish tracked were moving toward the intake opening. The directionality study indicated that a variable and sometimes low percent of tracked fish passing through the acoustic beam were actually entrained.

Phase III Fixed-Aspect Hydroacoustics Studies

Introduction

Fixed-aspect hydroacoustics sampling was conducted on pumpback units 5-8 during the Phase III study period at the Richard B. Russell Dam. Acoustic sampling was designed to provide information on individually tracked fish during low density events, and on schooling fish during high density events. The relationship between the fixed-aspect hydroacoustics and netting provides predicted entrainment for pumping when net data are not available, and supplements the net information with spatial and temporal trends. Acoustic sampling was also conducted on generation unit 4 during June 1996 to determine the feasibility of multiple beam acoustic tracking to determine direction of fish movement and assess the potential for using this technique to better predict fish entrainment during generation at Richard B. Russell Dam.

Methods

Hydroacoustic equipment and calibration methods for the Phase III study period were similar to the Phase II study. Sampling was conducted with a Biosonics ES2000 Echosounder generating five 0.4 ms pulses per second at 420 kHz for each transducer. Elliptical single-beam transducers were replaced with circular dual-beam transducers on all units in June 1996 to reduce noise and obtain target strength information for all units. Source level, receiving sensitivities, receiver gain, and wide beam drop-off for each echosounder and transducer combination were based on the most recent calibration of the equipment by Biosonics, Inc. (Table 6-1). All transducers were also field calibrated on a monthly basis (Table 6-2) and checked for any cable, transducer, or sounder replacement or modification. All field calibration adjustments were reviewed, and jointly agreed upon by WES and Aquacoustics, Inc. Bottom range and any noise or apparent structure on the echogram was recorded for each transducer. These values were compared with previous values for any divergence, indicating system malfunction. The threshold for an acceptable echo was set at -56 dB to avoid echo saturation from large targets, and allow a sufficient signal to noise separation to distinguish background noise scatterers from fish targets. A single transducer was mounted in front of each intake bay (2 transducers per unit) on a pivoting framework attached to the dam and aimed towards the intake bay at approximately 20 and 30 degrees from vertical on units 5-6 and 7-8, respectively.

Biosonics data collection software ESP_DBM and ESP_EIM was used to collect and filter data for tracked fish and multiple targets from schooling fish, respectively. Data was collected from all pumpback units by slow multiplexing between even and odd number transducers every 225 seconds, and fast multiplexing (sequentially switching) among the 4 even or odd transducers. Data collection began prior to unit startup and continued until after unit shutdown for every pump event.

During processing the data were analyzed utilizing either tracking or integration techniques. Tracking identified individual fish based on the pattern of multiple hits from an individual fish as it passed through the acoustic beam. Each file processed by echo tracking was reviewed to ensure that target groups enumerated as fish met mean target size (-30 to -50 dB) and a range weighted number of hits criteria. Real-time tracking data was edited using the ESP_ECHO autotracking option and manual inspection. All data files were edited for structure and pumping times. Integration estimated fish passage by summing total reflected voltage and scaling the summed voltages by the mean voltage returned by a single fish. Echo integration was used to process data during May, and July through October, 1996. Noise caused by the entrainment of silt during 4 unit operation reduced the effectiveness of echo tracking during May, and a large number of small threadfin shad entrained during July through October resulted in a similar problem for echo tracking. Integration data was output using Biosonics software READEIMC.EXE. The average fish size was determined by the average back-scattering cross section for all fish tracked during each month. The total number of fish was calculated based on multiplying the relative density (number of

fish/m³) by the intake width (m), the intake velocity (m/sec), the depth interval (m), and the time interval (sec).

Quality control and assurance guidelines were followed to maintain the integrity of the hydroacoustic database and insure no significant variance between hydroacoustic editors. A one hour data file for a single transducer was randomly selected from each pump event and independently edited by a second editor. A difference between editors of greater than 20% in the total number of fish triggered retracking of the file by both editors. If no consensus was reached the entire pump event was retracked.

Net and acoustic samples collected during Phase III pumpback operation at Richard B. Russell Dam were combined with those paired samples collected from April 1995 through Phase III startup for regression analysis. Pumpback entrainment data collected prior to the Phase III study were used to develop the regression equations reported and were not expanded to predict entrainment rates over that period. Samples collected from April through August 1995 with missing bottom strata were not included in the analysis. PrePhase III and Phase III data were combined to calculate regressions after determining the Phase III regression slopes were not significantly different than data collected previously. The hypothesis for comparison of net and acoustic gear assumes the gear types will perform similarly under varying entrainment rates and species compositions. The regression incorporates these variables when both gear types are effectively sampling the entrained population.

The hydroacoustic entrainment estimates by event were compared with the paired net entrainment estimates by unweighted least squares regression. Data from each unit was regressed separately to provide a regression by unit. The predicted net entrainment rates by unit by month were compared with the Phase III net entrainment rate estimates by GLM/ANOVA to compare the means of the samples.

Fixed-aspect hydroacoustic equipment and methods for generation entrainment sampling were similar to the pumpback study. The data used in this report were collected from April, 1995 through February, 1996. A dual-beam transducer was mounted in front of each unit and data was collected on all units by slow multiplexing between even and odd numbered transducers. Both tracked fish and echo integration data were collected and processed.

A short term research initiative was conducted on conventional generation Unit 4 over a two week period in mid-June, 1996 to determine whether hydroacoustics could determine direction of movement for fish near the generation intakes. Paired single beam transducers were installed by aiming one transducer away from the intake and 10 degrees from vertical, while aiming the second transducer away from the intake and 15 degrees from vertical. This configuration allowed fish targets to be tracked and the direction of fish movement to be determined near the intakes. Fish tracking parameters used in counting fish were similar to the 1995 conventional generation parameters.

Pumpback Results

Regressions between net entrainment rates and hydroacoustic rates were significant for all units (Figures 6-1 to 6-4), although the Unit 7 regression changed in June 1996 and the regression prior to mid June 1996 was significantly different at the 95% level than the regression after June (slope changed from 1.673 to 26.972). These regressions were used to predict monthly mean entrainment rates and the predicted values were compared to the net entrainment rates by unit and month (Table 6-3). The predicted net entrainment rate ($\bar{x} = 1,153$) based on the regressed hydroacoustic data fell within the confidence limits calculated from the net entrainment rates ($\bar{x} = 1,066$) during Phase III operations (Table 6-4), and ANOVA determined the means for the net and predicted net values were not different for the Phase III period for the 4 units.

Differences in regressions for unit 7 before and after mid June 1996 occurred when the entrained fish species composition changed to primarily threadfin shad. The transducers on units 7 and 8 are located 17 feet higher in the water column than the transducers on units 5 and 6 because of the vortex hood over half of unit 7 and all of unit 8. Although the threadfin shad were entrained by all units, the depth they passed through the acoustic beam varied due to the placement of the transducer and the vortex hood. A total of 57% of the fish entrained by Units 5 and 6 during the July through October period when threadfin shad entrainment was highest passed through the acoustic beam at an elevation above the depth sampled by transducers on units 7 and 8. Fish entrained by unit 8 may have been drawn below the vortex hood where they were more effectively sampled, however, while only one of the 2 intake bays on Unit 7 is restricted by the vortex hood the transducers on both intakes are placed at the lower elevation. The change in species composition and vertical distribution of fish during entrainment defined the 2 different regressions for unit 7 when the hydroacoustic sampling efficiency became dependent on the depth of fish in the water column.

Separate regressions for only Phase III data were not constructed. Although the data collected during Phase III was able to predict net entrainment values similar to the net values obtained during this period, the regression lines were poor predictors for pre-Phase III net data. The short time period with small variances in entrainment rates, compared with 1995, proved to be a poor predictor over the conditions observed over the longer time period sampled. The correlation coefficients were also higher for units 7 and 8 by including the pre-Phase III data, although the coefficients for units 5 and 6 were less when including all available data. Inclusion of pre-Phase III data provides additional information relative to high passage events not sampled during Phase III, a complete annual period, as well as, between year variability that existed due to differences in operation and changes in entrainment species composition.

Temporal changes in entrainment were evident during the Phase III study period. The highest entrainment events occurred from mid July through September for all units (Figures 6-5 to 6-8). A single pump event for Unit 5 on September 3 entrained nearly 12% of the total entrainment for that unit over the

Phase III sample period. Similar high entrainment events occurred for Unit 6 on July 28 and August 4 when nearly 40% and 17% of the total fish on Unit 6 were entrained, respectively, and also for Unit 7 on July 21 when nearly 27% of the total for that unit were entrained. Entrainment on Unit 8 did not fluctuate as much as the other units. When based on the number of hours of operation by month, the highest entrainment occurred during the months of July, August, and September (Table 6-5). Entrainment was highest during September on Unit 5 and August on Unit 6. The highest entrainment months for Unit 7 were July and August, while July and September were highest for Unit 8. Entrainment was lowest in April and June for all units.

Entrainment also varied among units during Phase III testing. All units operated nearly the same amount over the Phase III period (Table 6-6), however, operation was not equal across units during each month of testing. Units 5 and 6 operated more than units 7 and 8 during April and units 5 and 8 operated less while Unit 7 operated more in August. Entrainment totals by Unit 8 were always less than expected based solely on hours of operation. For example, Unit 5 contributed 29.2 percent of the total pumpback operations during the month of April but entrained 40.9 percent of the monthly total (Table 6-6). Conversely, entrainment total was approximately 1.9 times higher for Unit 5 during September and 2.3 times higher for Unit 6 during August than expected based solely on the proportion of pumping that each unit contributed to the power plant. Over the Phase III test period entrainment by Unit 6 was nearly 1.6 times the expected entrainment, based on hours of operation.

Net sampling, because of logistic considerations, was restricted to 16 days per month at one unit or one bay of one unit whereas hydroacoustics could sample all bays and all events. We compared hydroacoustic estimates of entrainment with net estimates of entrainment for those days in which netting was performed (Table 6-7). Net expansions were calculated by multiplying the number of hours of pumping times the overall mean of the mean passage rates for each event. Unit-by-unit passage using net data was estimated by taking the number of hours of operation that a particular unit was operating with concurrent netting (even though the netting may have been at a different unit). This estimate of unit specific net entrainment was paired to direct estimates of passage obtained from the hydroacoustics monitoring system. This comparison indicates that when netting samples a significant proportion of total pumping time then consistency with hydroacoustic estimates is high. For example, in April, net sampling was conducted 85.2 percent of the total time that unit 5 was in operation. Total unit 5 net entrainment is calculated as: $\text{APRIL MEAN NETTING ENTRAINMENT RATE} \times \text{NUMBER OF HOURS OF OPERATION FOR THE POWER PLANT} \times .852$. Total concurrence in passage estimation between hydroacoustics and netting is indicated when the two percentages are identical. For April on unit 5, the estimated relative passage of 82.7 percent based on hydroacoustics is close to the net based estimate of 85.2 percent indicating concurrence between the two gears. Conversely, in July, Units 6 and 7 did not have concurrence between hydroacoustics and netting. This deviation in occurrence is likely attributed to two reasons. First, pumpback operation is considerably less in April than July, therefore increasing the

proportion of net sampling to total operation. Secondly, the entrainment of threadfin shad in July is variable with occasional high events which increases the likelihood that passage estimates based on netting will decrease in accuracy (Figure 6-7). Subsampling with nets predicts entrainment well when variability is low and the percentage of events sampled is high.

The number of units pumping during a pump event was related to the hydro-acoustic entrainment rate during the April through June period of Phase III testing. Comparisons between 1,2,3 and 4 unit pump operations by ANOVA of the mean entrainment rates (number of fish/hour) indicate significantly lower entrainment rates for single unit pumps over multiple unit pumps at the 95% level (Table 6-8). Net data show similar trends, although the sample size is insufficient to test 3 unit pumps. Sample comparisons were restricted to the April - June 1996 period due to the lack of single unit pumps after June. The entrainment rate was significantly higher after June so all data could not be combined. Mean entrainment rates during 2, 3, and 4 unit pumps were not significantly different.

Entrainment rates were compared between pre-generation and non pre-generation pump events to determine if Richard B. Russell conventional generation affected pumpback entrainment rates. When conventional generation operations preceded pumpback operation within a 24-hour period the pump event was classified as a pre-generation pump event. Pump events where there was no generation during the previous 24-hour period were classified as non pre-generation pump events. Data used in this analysis are unweighted by unit operation and therefore restricted to the months May-August 1996 when the number of hours of pumpback operation were similar among units. Comparisons were made among units by combining 2, 3 and 4 unit pump events to calculate a mean entrainment rate by month (Table 7). Entrainment rates for all pumpback units were higher during non pre-generation than pre-generation unit pump events except during the month of June. Although non pre-generational unit events comprised only 13% of the total unit pump events during the period of highest entrainment (July-August 1996) for Phase III, 78% of the events with entrainment rates >10,000 fish per hour were non pre-generation pumps.

Vertical distribution of entrained fish sampled by hydroacoustics changed through the Phase III testing period. Entrained fish were distributed through the water column sampled (308 - 269 feet on units 5 and 6 and 297 - 266 feet on units 7 and 8) in April, May, and June, were near the surface in July and August, and were again distributed throughout the water column in September and October (Figures 6-9 to 6-12). A total of 92% of the fish entrained from July through October by units 5 and 6 entered the acoustic beam above the intake opening while 57% of the fish entrained by units 7 and 8 were above the intake opening. The pumpback intakes at RBR occupy depths from 266 to 286 feet elevation. Units 5 and 6 were sampled 21 feet above the top of the intake to near bottom, while units 7 and 8 were sampled 1 foot above the top of the intake to near bottom from April through June and 9 feet above the top of the intake to near bottom from July through October.

Conventional Generation Results

Fixed-aspect hydroacoustic entrainment sampling during conventional generation showed no relationship between numbers of fish counted with acoustics and numbers of fish caught in the nets (Table 6-10) (Figure 6-13). Expansion of the data using the tracked fish regression for April through December 1995 and the net entrainment rates for January through March 1996 would predict 4,147,350 fish entrained during this period, however, most of this entrainment is likely moribund threadfin shad.

The entrainment estimates for single unit vs. multi-unit operation are based on 12 single unit events, and 56 multi-unit events involving either 5, 6 or 7 unit operations, from April through September, 1995. Results indicate that the entrainment rates for single unit events are 3.4 times higher than multi-unit events. However, the sample size for single unit events is small and the data are not collected uniformly over the entire six month period, so the rates may be indicative of the short term trends in entrainment that occurred when seven of the 12 samples were collected during a single week in May. Further interpretation of the data is not warranted due to the non-random sample design and the poor interpretation of the hydroacoustic data without directional fish tracking.

Conventional generation data collected over a two week period in mid-June 1996 during the Phase III study period was analyzed to determine direction of fish movement in front of unit 4. Results showed that two to twenty-five percent of the fish tracked were moving toward the direction of the intake. These results indicate that a variable and sometimes low percent of fish tracked during the 1995 conventional generation data collection were actually entrained.

Discussion and Recommendations

Hydroacoustics has proven to be a viable sampling tool to measure fish entrainment at Richard B. Russell Dam during pumpback operations. Results from the Phase III study period showed that the fixed-aspect system accurately predicted monthly entrainment within the 75% confidence intervals required, sampled approximately five times the number of unit hours, provided information on vertical distribution of fish in the forebay, and cost less to operate than netting. The following recommendations are made to optimize future sampling needs using hydroacoustics at the Richard B. Russell Project:

- Conduct further analysis on data collected during the Phase III study period to determine what percent of the data needs to be processed each month to accurately predict entrainment.
- Monitor pumpback entrainment for two years to evaluate trends.

- Conduct monthly gillnet sampling and purse seine sampling from March-September in the immediate tailrace area to collect species composition information during entrainment sampling.
- Perform annual system calibrations on all hydroacoustic equipment used.

7 Threadfin Shad and Blueback Herring Population Estimates

Summary

Complete assessment of the effects of pumped storage operation requires that population numbers of abundant forage species be determined. However, it is difficult to estimate numbers of small, open water species using conventional fishery collecting gear. Mobile hydroacoustics surveys were used to estimate numbers of blueback herring and threadfin shad in JST Lake. Mark-recapture methods were used to estimate the number of adult blueback herring.

Mark-recapture methods involve capturing a significant proportion of a population of unknown size, marking the captured individuals so that they can be later identified, releasing them into the population at large, capturing members of the same population at a later time, and determining the proportion of the recaptured population that is marked. The population size can be estimated from the simple proportionality of (total recaptured individuals)/ (recaptured marked individuals) times the number of fishes initially marked. The mark-recapture study determined that the number of adult blueback herring in JST in May of 1996 was 84,165,737 with 95% confidence limits of 70,110,058 to 100,830,552. The mean length and 1 standard deviation of fish during marking was 140.3 mm (5.5 in.) +/- 5.0 mm (0.20 in.), during the May-June recovery was 148.8 mm (5.9 in.) +/- 6.1 mm (0.24 in.), and during the August recovery was 153.3 mm (6.0 in.) +/- 6.9 mm (0.27 in.). The mark-rapture study is included as Appendix I.

Mobile hydroacoustics surveys utilize scientific grade equipment so that fish depth and acoustical size can be determined with great accuracy. Mobile hydroacoustics is able to sample large areas of the lake relatively easily so that definitive statements can be made about the number and distribution of fishes that commonly occur in the open waters of a lake. However, hydroacoustics sampling cannot determine the species composition of fish. Species composition information must be provided by other gear types.

The open water area of Strom Thurmond Reservoir was sampled in March and August 1996 with mobile hydroacoustics and several types of nets to estimate species composition, population abundance, and size-structure of small, pelagic fishes of JST Lake. Sampling was conducted after sunset by randomly traversing the open water region of the reservoir at a speed of 4-5 mph. Species- and size-composition information from concurrent netting provided data to apportion hydroacoustics targets as blueback herring, threadfin shad, or other fish species.

Results of the two mobile hydroacoustic surveys can be found in Appendices G and H. The spring fish abundance estimate was 138,129,575 and the summer estimate was 1,364,104,921 fish, nearly ten times the spring estimate. During the springtime sample, netting indicated that all species were more or less evenly distributed throughout JST Lake and that the proportions of blueback herring and threadfin shad were approximately equal (57 million threadfin shad and 68 million blueback herring). The length frequency distribution of threadfin shad indicates that 98 percent of these were shad spawned in 1996.

The threadfin shad population increased from 57 million to 1,322 million from the spring to summer estimate whereas the blueback herring population estimate declined from 68 million in spring to 42 million in August. The August sample included a significant increase in juvenile fish (less than 90 mm long) but a precipitous decline in fish greater than 90 mm. The mean size for fish estimated in the March hydroacoustics sample was 120 mm with no indication of the presence of juveniles. The March hydroacoustics population estimate and the May mark-recapture population estimate fall within each others 95 percent confidence limits and it is reasonable to expect many of the blueback herring in the 120 mm size estimated from the March mobile hydroacoustics estimate to recruited into the 140 mm size range of marked fish in May. However, the August mobile hydroacoustics blueback herring population estimate appears to be inconsistent both with the March mobile hydroacoustic estimate and the May mark recapture estimate. The discrepancy can be best explained by examining the netting data used to apportion the hydroacoustics targets into species-specific abundance estimates and considering the distribution of blueback herring within JST Lake in August. Unlike in the spring, when blueback herring can be expected to occur in much of JST Lake, their distribution (particularly of adults) in August appears to be restricted to cooler, deeper water. The likelihood of adequately sampling blueback herring in August when they are concentrated into certain regions of JST Lake is less than when they are more uniformly distributed in spring. Also, the netting data used to apportion hydroacoustics data by species is considerably less balanced in the summer when the number of small, open water fishes are overwhelmingly threadfin shad. For example, blueback herring often represent less than 3 percent of the purse seine sample (Table 7-1) and the catch per net set for the deep sets of other types of netting is also generally low. Consequently, August relative abundance estimates for blueback herring can be significantly impacted by a shift of small numbers of blueback herring. For example, only one blueback herring in the 60-90 mm size class was captured in all of the deep net sets, whereas 49 out of a 200 fish subsample in a tailrace purse seine sample were in this same size range. Nets are a notoriously variable sampling gear and generally

provide a poor basis for population estimates. While the netting probably adequately describes pattern in year class progression and general spatial distribution patterns, it is unlikely to provide an adequate basis for apportioning mobile hydro-acoustics targets into species.

Table 7-1

August Summary Proportions of Blueback Herring in Purse Seines

Purse Seine				
Size Class (mm)	Number Samples Combined	Blueback Herring Number	Threadfin Shad Number	Mean Percent Threadfin Shad
<60	7	39	1562	97.6
60-90	6	49 ¹	151	75.5
90-130	2	0	4	100
>130	2	0	0	0

¹ - of the 6 samples, 1 contained 48 blueback herring (tailrace station), 1 contained 1 blueback herring, and 4 had 0's.

8 Blueback Herring Commercial Catch

Summary

Blueback herring are an abundant commercially and recreationally important bait fish. Commercial bait dealers capture blueback herring in large numbers and sell them to recreational fishermen and many recreational fishermen capture blueback herring for bait. To fully assess the impacts of pumped storage operation on blueback herring it is also important to describe and quantify sources of mortality in addition to entrainment.

Standard creel survey methods were employed to obtain commercial catch for blueback herring. Nighttime interviews were conducted at the boat ramp immediately downstream of Richard B. Russell Dam on the South Carolina shore for completed trips only. An instantaneous count of the total number of commercial fishermen was made in the tailrace at the peak of effort each night. Up to five surveys per week were conducted during months of high commercial activity and at least one survey per week was conducted from July 1994 through May 1996.

Catch and effort peaked between August and October, the period when blueback herring are concentrated in the tailrace due to warm and stratified conditions throughout the reservoir. Estimated monthly catch in the tailrace of Richard B. Russell Dam varied from 0 to 177,525 blueback herring. Estimated commercial harvest of blueback herring in the last half of 1994 was 542,854, in all of 1995 was 555,377, and through May of 1996 was 15,820. This study is attached as Appendix J.

9 Sport Catch Creel Survey

Summary

Fishermen harvest information, commonly called creel information or creel surveys, describes the temporal and spatial patterns in take of sport fish. Typically creel surveys provide information such as catch per unit effort and total harvest although the South Carolina DNR creel survey of J. Strom Thurmond Lake has included a questionnaire on the attitudes of fisherman towards pumped storage operations. This information can be employed to evaluate the effect of additional mortality sources, such as turbine mortality, on the population structure of common sport fishes. It can also be employed to describe how project operation can effect angling. The South Carolina Department of Natural Resources (SCDNR) conducted creel surveys on Richard B. Russell Lake and J. Strom Thurmond Lake from January 1, 1991, through October 31, 1996 (Appendix K). The Georgia Department of Natural Resources has conducted creel surveys in the Richard B. Russell tailwater from 1988 through 1996 (Appendix L).

Results of the SCDNR creel survey indicate that most anglers targeted largemouth bass and crappie in Richard B. Russell Lake and that these two species were caught in greatest number both in terms of number and weight. Overall catch rates for all species combined ranged from 0.75 fish/hr (1995) to 0.94 fish/hr (1994). In J. Strom Thurmond Lake, most anglers targeted largemouth bass, crappie, and hybrids. However, bluegill, crappie, largemouth bass, redear sunfish, hybrids, and white perch comprised the majority of the harvest from 1991 to the present by number and crappie, largemouth bass, hybrid bass, and striped bass by weight. For the two reservoirs together, anglers have spent an average of approximately \$10 million per year on gas, bait, food, lodging, and miscellaneous items since 1991. Patterns for those portions of 1996 documented in the reports did not appear to be significantly different in whole lake creel patterns. The GADNR creel indicates that *Morone* sp. (hybrid bass, striped bass, white bass, and white perch) dominate the creel in the tailwater of Richard B. Russell Dam. There appear to be differences in angler success patterns in the tailwater area of Richard B. Russell Dam for striped bass and hybrid bass in 1996 with apparent reductions in angler harvest. The results of the SCDNR survey on JST indicated that a majority of the fishermen (58 percent) did not think that pumped-storage operation impacted fishing success. The survey also indicated

that a majority of the fishermen on RBR (53 percent) felt that pumpback operation did not impact their fishing success. Those anglers in both lakes that felt pumpback operation had impacted fishing also felt that the numbers and size of fish caught had been reduced; however, many also felt that they did not know the effects of pumpback operation on their fishing success.

10 Improvements to the Fish Protection System

At the end of Phase II, the fish protection system consisted of the following components: (a) a high frequency sound repulsion system that repels blueback herring from the pump-turbine intakes (from the face of the downstream side of the dam downstream to a distance of about 50m); (b) banks of high-pressure sodium lights located on the Georgia shoreline where water velocities are reduced; (c) a bar screen veneer composed of panels of stainless steel wedge-wire on 2-in. centers banded directly to the trashracks; and d) operational guidelines that eliminate daytime pumping and recommend that pumping not begin before one hour after official sunset and end prior to one hour before official sunrise. Evaluations of the fish protection system indicate that it had substantially reduced fish entrainment and should be an integral part of pumped storage operation at RBR Dam during Phase III sampling. Prior to the beginning of Phase III the protection system was improved by expanding the sound repulsion system to include Units 7 and 8, the sound repulsion system was reconfigured, the light system was expanded on the Georgia shore and a new bank of lights were installed on the South Carolina shore, the bar rack veneer was inspected and modified where needed to eliminate gaps around the outside border of the trashracks where the center-line distance between the bar rack veneer members exceeded two inches, and a rock berm was constructed about 600 feet downstream of the dam that extended laterally about 300 feet into the channel to redirect the flow to eliminate the vortex that appeared to entrain blueback herring into Unit 8. Although more data are required to confirm the exact efficiency of the fish protection system, no significant entrainment events were observed during Phase III sampling similar to what was observed on a number of occasions during Pre-Phase III sampling. The continued success of the fish protection system suggests that the present configuration of the fish protection system is optimal and should be employed during commercial level operation.

11 Mobile Hydroacoustics Summary

Summary

Mobile hydroacoustics surveys utilize a scientific grade system that functions much like a depth finder except that the range and acoustical size of fish can be determined and recorded with great accuracy. In a mobile hydroacoustics survey, a transducer that emits high frequency sound waves is attached to a boat. The boat transverse a set of transects of known length. Each time the boat passes over fish, the return echos are recorded and later analyzed. From these echos it is possible to expand the number of fish sampled by the survey to estimate the number of fish in the lake. Mobile hydroacoustics sampling is noninvasive (does not damage the fishes) and large areas of the lake can be sampled relatively easily so that definitive statements can be made about the number and distribution of fishes that commonly occur in the open waters of a lake. Mobile hydroacoustics is particularly useful for sampling the numbers and spatial distribution of small open-water fishes such as threadfin shad and blueback herring that are particularly susceptible to entrainment.

Mobile hydroacoustic surveys were conducted in the tailrace and tailwater areas of the Richard B. Russell (RBR) Dam concurrently with the collection of gillnetting and electrofishing baseline data monthly over a ten-year period spanning 1986 to 1996 (provided as Appendix M). The mobile hydroacoustics surveys were utilized to provide information on the distribution of fish over time and to compare the pre-pumpback and pumpback fish distributions. Mobile hydroacoustics was also used to determine monthly population estimates for small open water fishes below RBR Dam in 1996.

Monthly mobile hydroacoustic surveys were performed on established line-transects in the RBR tailrace and tailwater areas. This collection method was used consistently during the 10-year study period. To ensure proper repetition of survey transects between collection events, both start and endpoint of each transect was marked with a reflective marker, and with latitude and longitude position using a Ground Positioning System (GPS). The RBR tailrace area was defined as the lake area immediately adjacent to the base of the Russell Dam and extending

approximately 0.25 miles downstream of the dam. This area was sampled by twelve parallel transects that began on the Georgia bank and extended to the South Carolina bank. The RBR tailwater area was defined as the lake area located approximately 0.25 to 4.5 miles below the Russell Dam. Surveys in this area were performed along eleven parallel transects extending from the Georgia bank to the South Carolina bank. Mobile hydroacoustic population estimates were performed in 1996 to provide an estimate of the open water fish population residing in the RBR tailrace and tailwater areas. The surveys were conducted after sundown during a non-generation period and encompassed the area from the RBR Dam downstream to the mouth of Russell Creek.

An in depth review of the ten-year hydroacoustic database was performed to detect missing data points and possible errors. The electronic database was obtained from WES and a copy of the original collection sheets were obtained from the various contractors used during the study. These data were compared to detect missing data points in the database. Changes to the database were made to correct processing of the bottom in the data file during analysis or to correct scaling of the output. The errors detected during the quality assurance check of the data base were corrected using the best available information. These corrections and missing data points did not appear to affect the quality of the data or its usefulness for application to the project.

Seasonal distribution of fish density in the RBR tailrace and tailwater areas was analyzed to observe overall trends. Overall trends indicate low fish densities during the cooler winter months, followed by an increase in fish density during the spring months. Fish densities tend to peak between May and August, and decrease in the fall as water temperatures cool. This pattern can be most easily explained by the movement of fish towards the RBR Dam in the spring and the annual recruitment of young fish during the summer. The nighttime sampling surveys indicate that the maximum fish densities occurred during 1994 and 1996. The nighttime data indicated slight shifts in fish distribution throughout the year. The highest densities of fish were observed in the area immediately below the RBR Dam during the spring and summer months. Fish densities increased downstream as the water temperatures cool in the fall and winter months. The daytime data indicated the same general trend. In most of the surveys, the mean monthly depth of fish targets was deeper during daylight surveys than night surveys. The data indicate that daytime sampling detected only 25 percent of the fish densities observed during nighttime sampling. Statistical analysis of day vs night data indicates that approximately half the number of transects were necessary to predict density at night than during daylight; tailrace night - 32 transects, tailrace day - 69 transects, tailwater night - 18 transects, and tailwater day - 44 transects. Based on these analyses it was determined that nighttime data was a more reliable predictor of actual fish density in the tailrace and tailwater areas.

During the 10-year study period, many environmental and physical changes occurred in the project area including; drought, the addition of tailrace lights, tailrace channel dredging, the addition of fishing berms, the "Unit 8 vortex berm," and project generation and pumpback operations. The 10-year data base was

reviewed to detect changes in the tailrace and tailwater fishery associated with these changes. Although the study was not originally designed to address these changes, portions of the data base were appropriate for this analysis.

A severe drought was experienced at the project in 1986-89. The low water levels in the RBR tailrace may have accounted for the low densities of fish in the tailwater during these years by: (1) low water levels would have provided less actual habitat and would not be able to hold as many fish; (2) the shallow water level would have decreased the area of the water column sampled by hydroacoustics since the transducer did not sample the top 6 feet of the water column; and (3) the shallow bar in the lower tailrace area would have restricted fish movement.

Since electrical generation at the RBR project is related to turbine operation and tailrace flows, the total generation by month was examined for trends in comparison with fish densities for the tailrace night samples. During years of relatively high generation, (1990, 1993, 1995, and 1996), fish densities in the tailrace area decline. Due to increased water velocities in the tailrace, it is likely that fish either repositioned into low velocity areas close to banks or possibly moved downstream to tailwater areas. The increased tailrace velocities would especially have an impact on juvenile populations residing in the tailwater, since their ability to fight the flows is lower than adults.

Another change that occurred during the study period was the addition of illumination to the RBR tailrace area. Lights were installed along the dam face, fishing pier, and along both banks of the tailrace. Based on the behavioral responses of blueback herring and threadfin shad to light, the hydroacoustic data was examined to observe any trends associated with increased lighting. The percent of the total number of fish in segments near the Georgia bank increased after installation of the lights. It was not determined if this relationship is statistically significant, or if lights were the only reason for this change in fish distribution in the tailrace.

Another influence that occurred during the study period was the physical change in the tailrace by dredging. The tailrace area was deepened by dredging during an eight month period that extended from September 1994 to March 1995. Hydroacoustic data from the periods before, during, and after dredging were examined to observe spatial changes in fish distribution throughout the RBR tailrace and tailwater that may be associated with dredging. Examination of both nighttime and daytime survey data revealed no spatial changes in the fish distributions in the tailrace or tailwater that can be related to dredging operations.

Pre-Phase III and Phase III project pumpback operations were undertaken during the spring of 1995 and 1996, respectively, at the RBR project. Variations in the monthly mean densities occurred over the 10 year period sampled and include densities lower during the Pre-Phase III and Phase III period than in 1994, although densities were lower in 1986-1987 and equally low in 1989-1990. Possible explanations for this decline in 1995 and 1996 include: increasing generation at RBR Dam flushing the tailwater, entrainment, natural variability of threadfin

shad and blueback populations in Thurmond Lake, or physical changes in the tailwater.

Monthly population estimates were initiated in January 1996 to provide an estimate of the number of fish in the RBR tailrace and that portion of the tailwater affected by pumpback operations. The population estimates allowed the number of fish susceptible to entrainment to be estimated during a 4 unit pumpback operation in the immediate vicinity of the intakes (above the boat exclusion buoyline) and in the tailwater area. This information was compared with the monthly hydroacoustic estimates of pumpback entrainment during the Phase III period. Hydroacoustic entrainment estimates related well to the mobile hydroacoustics fish population estimates for the 7 months in the Phase III period. Highest populations of fish occurred during July and August when entrainment of threadfin shad was highest. The entrainment estimates were regressed against the mobile hydroacoustic population estimates for the months where data were available, an $R^2 = 0.91$ with $P < 0.001$ indicates a good relationship exists for the Phase III test period. This relationship was also supported by the small mesh gillnetting. Catches of threadfin shad were substantially higher during moratorium sampling than during nonmoratorium sampling at the most upstream station of JST. Approximately 11.0 percent of the fish (predominantly threadfin shad and blueback herring) in the 1,344 acre area sampled were entrained monthly. The mobile hydroacoustic sample area represents less than 2 percent of the area of Strom Thurmond Lake, and the population estimates for this area in March and August represent 2.9 percent and 1.9 percent of the lakewide population estimates for those months. Entrainment estimates were also compared with line transect density estimates, however, the relationship was not as closely correlated as the population estimate data.

12 Population Modeling

Summary

The impacts of operating pumped storage at RBR Dam cannot be completely assessed by simply comparing the entrainment losses against estimates of population abundance. Risk assessment methods, combined with population modeling, must be used to quantify the risk that an impact may cause a population to decrease to extinction or to a threshold level. In this approach a mathematical model is used to describe the dynamics of a target species. Population vital statistics are randomly selected to predict 50-year population histories that appear to match the general pattern observed for the target species. This process is repeated up to 1000 times. The resulting trajectories can be analyzed statistically to determine the probability that over multiple runs a population may go extinct or reach a lower threshold. Losses resulting from entrainment can be placed in this same framework and the impact can be couched as an increase in the probability of extinction or an increased probability that the low threshold will be reached. Population model based risk assessment using the RAMAS population models was performed on the following five species/groups of fish: threadfin shad, blueback herring, black crappie, hybrid bass, and striped bass (provided in Appendix N). Threadfin shad and blueback herring are both short-lived and their growth is strongly regulated by density (i.e., expansion in numbers at high population levels is inhibited). Striped bass and hybrid bass are long-lived species whose abundance is maintained by stocking. Compared to the other four species, relatively little is known about the vital statistics of black crappie, a naturally reproducing sport fish within JST Lake.

Assessments were performed at two levels: Scenario A is based on entrainment data collected from August 31, 1993 to October 31, 1996 (includes high entrainment events observed between Phases II and III). Scenario A simulations include effects of average water year entrainment rates on each species population as well as the effects of more extreme entrainment rates to determine the sensitivity of the models. Entrainment for extreme events was obtained by adding 3 standard errors to mean entrainment rates for each month and expanding by the number of hours of pumping for each month. Scenario B simulations were restricted to evaluations of Phase III monthly rates projected to annual average water year entrainment. Scenario B simulations are based on the most complete data sets to simulate

commercial operation at RBR because: (1) entrainment rates and population vital statistics are available; (2) all fish protection system and channel modifications were completed and all systems remained constant during the testing period; (3) Phase III samples are the only entrainment data collected under conventional generation and water quality conditions that could be expected under commercial pumpback operation.

Results of the risk analysis are presented as the maximum risk (probability) that population levels will fall below baseline simulation results at least once over a simulation period of 50 years. Results of the risk assessments indicates that entrainment affects the five species to varying degrees.

Threadfin Shad. Population levels of threadfin shad appear to be unaffected by entrainment losses under Scenario B. Under Scenario A the worst case entrainment loss (mean rates plus 3 standard errors) performed as a sensitivity test indicates that the maximum risk of decline increases only 5 percent at a population level of 6 million adults. Even the worst-case entrainment conditions indicate a minimal impact on population levels the risk that the population will decline to any threshold is barely discernible from background.

Blueback herring. Population levels of blueback herring appear to be minimally affected by projected average year entrainment losses under either scenario with a maximum increase in the probability of decline of 7 percent and 3 percent, respectively, above background for Scenarios A and B. Under extreme entrainment conditions (mean entrainment plus 3 standard errors or 12 percent), the risk assessment modeling shows a maximum increased risk of 53 percent above background that the population will dip below 11.3 million fish at least once over a period of 50 years. The 12 percent entrainment scenario of the modeled baseline population ($0.12 \times 51.3 \text{ M} = 6.15 \text{ M}$) is 14 times higher than the dry year annual worst-case loss obtained from Phase III data.

Hybrid Bass. Population size under the projected mean annual entrainment total for Scenario A or B shows a stable population reduction of 10,000 fish and a maximum increased risk of decline of 3 percent. The maximum entrainment scenario of 6 percent increases the risk by 15 percent that the population will decline below 46,000 fish at least once over a period of 50 years. The 6 percent entrainment scenario of the modeled baseline population ($0.06 \times 270,000 = 16,200$) is over 7 times the projected dry year annual worst-case loss of 2,134 fish. Based on the model, the loss of hybrid bass can be completely compensated by increasing the stocking rate to 746,000 fish per year (20 percent increase).

Striped Bass. Population size under projected mean annual entrainment total for Scenario A shows a reduction of 10,000 to 20,000 fish and a maximum increased risk of decline of 7 percent. Scenario B entrainment produced a maximum increased risk of decline of 4 percent. The maximum entrainment scenario of 8 percent of the baseline modeled population increases the risk by 22 percent that the population will decline below 50,000 fish at least once over a period of 50 years. The 8 percent entrainment scenario is more than 4 times the projected

dry year worst case loss of 2,789 fish based on annual projections using Phase III data. Based on the model, the loss of striped bass can be completely compensated by increasing the stocking rate to 286,700 fish (28 percent increase).

Black Crappie. The black crappie modeled baseline population stabilized at a mean abundance of 350,000 fish. The average annual harvest of black crappie from 1983 to 1996 was 255,335 fish. The abundance of black crappie in 1994 was over 6 million based on the cove rotenone data. It is therefore unlikely that the model predicted baseline population is correct. The authors of the population model note that there is not sufficient data on the black crappie population in JST to produce a model with any certainty, and skepticism when reviewing the results is recommended.

13 Predictions of Future Entrainment

Summary

Entrainment samples provide estimates of the numbers of fish passing through the pump-turbines. These rates can be used to describe entrainment patterns during the period of sampling, but also can be used to project possible entrainment by taking the entrainment rate obtained from monitoring and expanding by the numbers of hours of pumpback operation that can be expected under different future hydrological conditions. The amount of pumpback operation that will occur in the future is partially dependent upon basin inflows. Higher basin inflows reduce the need for pumping operation to maintain the capacity of conventional generation. Expansions to predict entrainment (all adjusted for survival) to future operation are based on the hourly fish passage rate obtained from netting samples for each month multiplied by the unit hours of operation anticipated for wet, average, and dry water years. We emphasize that these projections are approximations because it is likely that reproduction and recruitment of fish within JST is also sensitive to hydrology so that different water years will exhibit differences in fish abundance and species composition. Species possibly impacted by turbine passage were evaluated using population modeling based risk assessment as described in a previous section. Impacts that are proportionally small are difficult to assess with population modeling because the impact is small relative to the uncertainty in population vital statistics. Various sensitivity analyses are conducted to determine how the use of a range of vital statistics would affect the results of the model. Entrainment numbers were also compared to population estimates and to commercial harvest, sport harvest and other sources of mortality to allow entrainment totals to be placed in a relative context. For example, projected entrainment of 4,842,477 fishes weighing 20010 kg are projected to be killed under worst case operations for April through October. This is 0.27 percent by number and 0.24 percent by biomass of the total of approximately 1.807 billion fish in JST with a biomass of 8.4 million kilograms estimated to occur in JST during the late summer (by convention, the time period when many reservoir fishery assessments are made) of 1996. For a 12 month entrainment scenario, approximately 0.45 percent (8,067,489) by number and 0.28 percent (23,434 kg) by weight of the fish in

JST Lake can be reasonably expected to be killed by turbine passage during a dry year.

Anticipated entrainment totals, corrected for survival, for the different water years differ substantially from 1,040,553 for a wet year to 4,842,477 under dry year conditions during April through October. For the entire year (adjusted for survival), entrainment is estimated at 1,125,431 for a wet year and 8,067,489 for a dry year. The average year predicted entrainment by number of 4,294,869 is close to the dry year prediction because the biggest difference between average and dry year conditions is in the amount of spring time pumping when the entrainment of fish by number is substantially less than in the late summer. However, the difference by biomass between dry water year entrainment (20010 kg) and average water year entrainment (16002) is greater because larger fish are entrained during spring and early summer pumpback operation.

Phase III Data Projected to Full Pumpback

Expansions to predict entrainment (all adjusted for survival) to future operation are based on the hourly fish passage rate obtained from netting samples for each month multiplied times the unit hours of operation anticipated for wet, average, and dry water years. Assessment of entrainment is made at a lakewide scale because the results of both mark-recapture studies for blueback herring and radio telemetry studies on striped bass and hybrid bass indicate that fish are widely distributed within the reservoir on an annual basis and are not restricted to one portion of the lake. Localized and seasonal effects on fish distributions are presented in the section on temperature habitat for striped bass. Tables 1-3 and 1-5 (not adjusted for survival) and Tables 1-4 and 1-19 (adjusted for survival) include columns in which both the numbers and biomasses of netted fish are expanded to predict entrainment under different water years (note that referenced tables are presented in section 1 of this report). The anticipated entrainment total losses, adjusted for survival, for the different water years differ substantially from 1,040,553 fish for a wet year to 4,842,477 under dry year conditions during April through October (1-3). For the entire year (adjusted for survival), entrainment losses are estimated at 1,125,431 for a wet year and 8,067,489 for a dry year (Table 1-19). The average year predicted entrainment by number of 4,294,869 fish is close to the dry year prediction of 4,842,477 because the biggest difference between average and dry year conditions is in the amount of spring time pumping when the entrainment of fish by number is substantially less than in the late summer. However, the difference by biomass between dry water year entrainment (20010 kg) and average water year entrainment (16002) is proportionally greater because larger fish are entrained during spring and early summer pumpback operation.

Entrainment samples provide estimates of the numbers of fish passing through the pump-turbines. Species likely to be impacted by turbine passage were evaluated using population modeling based risk assessment. Impacts that are proportionally small are difficult to assess with population modeling because the impact is small relative to the uncertainty in population vital statistics. Population

modeling based risk assessment is presented in another section. Entrainment numbers were also compared to population estimates and to commercial harvest, sport harvest (Table 13-1), and other sources of mortality to allow entrainment totals to be placed in a relative context. For example, projected entrainment of 4,842,477 fishes weighing 20010 kg are projected to be killed under worst case operations for April through October. This is 0.27 percent by number and 0.24 percent by biomass of the total of approximately 1.807 billion fish in JST with a biomass of 8.4 million kilograms estimated to occur in JST during the late summer (by convention, the time period when many reservoir fishery assessments are made) of 1996. For a 12 month entrainment scenario, approximately 0.45 percent (8,067,489) by number and 0.28 percent (23,434 kg) by weight of the fish in JST Lake can be reasonably expected to be killed by turbine passage during a dry year. These estimates assume that whole lake abundance estimates from 1996 are representative of abundances in other water years.

Population estimates (using two different methods) and commercial harvest data are available for blueback herring against which the entrainment totals can be compared. Mobile hydroacoustics provides a total spring-time population estimate of 68 million fish. Mark-recapture censusing techniques yielded an estimate of 84 million adults in May of 1996. A total of 294,110 blueback herring of all sizes are projected to be killed during maximum pumpback operation (projected dry year operations) during April through October and about 313,069 can be reasonably expected to be killed during an annual cycle. The entrainment mortality total for April through October represents 0.43 percent of the total blueback herring population. On an annual basis, the entrainment mortality total is 0.46 percent of the total blueback herring population in JST Lake. Commercial harvest for 6 months of 1994 is 542,854 fish and for the full year in 1995 is 555,377 fish. Harvest in 1995 was considerably reduced because of an abundance of the smaller size classes of fish that are not useable as bait by fishermen. Turbine mortality of blueback herring during pumping operation is substantially less than commercial harvest. The marked-recapture study to estimate the number of adult blueback herring in the lake sacrificed 144,227 adult fish which is 49 percent of the estimated mortality resulting from worst case pumpback operation.

Population estimates using mobile hydroacoustics are available for threadfin shad greater than 1.2 inches in both March and August of 1996. The March population estimate is 56,577, 931 fish and the August estimate is 1,322,185,433 fish. The estimated turbine mortality loss of threadfin shad under maximum pumpback operation during Phase III months is 4,426,610 or 0.33 percent of the total or for an annual cycle 7,035,204 individuals representing 0.53 percent of the total numbers using the August population estimate. Threadfin shad have great reproductive potential and typically exhibit "boom and bust" cycles particularly when reduced winter water temperatures result in winter kill of this species. The August estimate is used because entrainment of threadfin shad is highest in August and September during their period of maximum abundance.

No direct population estimates are available for black crappie, white perch, striped bass, or hybrid bass. However, creel surveys are available against which

entrainment of harvestable sizes of these species can be contrasted. In addition, routine gillnet surveys have been conducted for 11 years as part of baseline studies in JST Lake and offer a gage against which to measure pumpback entrainment at Richard B. Russell Dam. Stocking goals are also known for striped bass and hybrid bass and can be used as a crude population estimate against which entrainment can be compared.

Under worst case (dry year pumping operation), 55,618 total and 19,619 harvestable white perch are estimated to be killed by entrainment or impingement during the biologically active (Phase III) time period. This compares to an estimated total of 4,184,270 white perch obtained from cove rotenone expansions for 1994, the first year in which white perch become a significant proportion of the JST fish community. White perch show the greatest potential for impact of any species investigated with 1.33 percent of the population being killed by pumping operation from April through October. Separate annual estimates of entrainment mortality for white perch are not presented because 98 percent of the entrainment of this species occurs during the April through October time frame (Table 1-17). Although lake wide numbers provide no evidence of impact, sport harvest of white perch for January through October of 1996 was estimated at 67,816 which is more than three times the entrainment totals of harvestable-size fish projected during worst case operation (Table 13-1). White perch are the fish population most likely to be impacted by pumped storage operation; however, they have not been identified as a desirable sport fish. As an additional consideration, it is likely that the population estimate used in the analysis (1994 cove rotenone areal expansions) substantially underestimate the abundance of this species. The sport catch for this species was 3,900 in 1994 compared to 67,816 in 1996, suggesting an order of magnitude increase in the number of harvestable white perch in the three year period. Concomitantly, baseline monitoring using gillnets shows that the catch rate for this species has increased at all JST stations from 1992 to 1996.

Black crappie entrainment mortality under worst case pumping scenarios is estimated to be 33,155 fish with 2,294 fish being of harvestable size. Long-term sport harvest of black crappie from 1983 to 1996 averages 255,335 fish/year with 203,032 black crappie caught in 1996. Entrainment mortality loss of harvestable-sized fish is only 0.90 percent of the long term average sport catch and 1.13 percent of the estimated sport catch in 1996 (Table 13-1). The total number of black crappie entrained is 0.52 percent of the long-term average abundance of black crappie in JST Lake of 6,428,593 and 0.23 percent of the over 14 million black crappie that were estimated for JST Lake in 1994, the most recent year in which cove rotenone data are available. Separate annual estimates for black crappie are not presented because 99 percent of the entrainment mortality loss of this one species occurs during the April through October time frame (Table 1-17).

Striped bass entrainment and impingement mortality under April-October worst case pumping scenarios are estimated to be 1124 fish (1056 entrained and 68 impinged) with 557 being of harvestable size (9-14 in. long) and 37 being of desirable size (15 in. long or longer). For an annual cycle, 1484 striped bass can be reasonably expected to be killed by entrainment and mortality (1394 by turbine

mortality and 90 by impingement) with similar relative size composition presented for the April through October time frame. The total population size of striped bass in JST Lake is unknown, although the management goal is to have an abundance of 3 striped bass per acre of lake area. Using this as a general guide approximately 225,000 catchable striped bass could be reasonably expected to occur in JST Lake. The worst case April through October mortality total of 594 for the two largest size-groups of striped bass is 2.6 percent ($594 / 225,000$) of the management target. The long term average sport harvest of striped bass is 18,504 fish/year (Table 13-1). April through October mortality of the largest two size classes of striped bass is 3.2 percent of harvest and mortality of the largest size group of striped bass (probably most representative of sport harvest) compared to the sport harvest is 0.020 percent ($37 / 225,000$). Routine and moratorium gillnetting (an accepted fishery assessment tool) has been conducted in JST Lake from 1986 to the present to provide relative estimates of spatial and temporal patterns of distribution of large, active fishes such as striped bass and hybrid bass. Average catch of striped bass in gill nets is 187 fish/year with 59 percent in the desirable length category (15 in. long and longer) or 110 fish/year compared to 37 fish/year of the 15-in. and larger length group entrained by the dam. Remarkably, the effects of the baseline netting program has substantially greater impact on the numbers of the largest length group of striped bass than does pumped storage operation under worst-case (dry year) operations.

Hybrid bass entrainment and impingement mortality under worst case pumping scenarios are estimated to be 616 fish (536 by passage mortality and 80 by impingement) with 329 being of harvestable size (9-14 in. long) and 111 being of desirable size (15 in. long or longer). For an annual cycle of operation, a total of 1016 hybrid bass can be reasonably expected to be killed (884 by passage mortality and 132 by impingement). The total population size of hybrid bass in JST Lake is unknown, although the management goal is to have an abundance of 7 hybrid bass per acre of lake area. Using this as a general guide approximately 525,000 catchable hybrid bass could be reasonably expected to occur in JST Lake. The worst case April through October mortality total of 440 (360 by passage mortality and 80 by impingement) for the two largest size-groups of hybrid bass is 0.08 percent of the management target density. The long term average sport harvest of hybrid bass is 60,304 fish/year. April through October mortality of the largest two size classes of hybrid bass (440) is 0.73 percent of harvest and mortality (111) of the largest size group of hybrid bass (probably most representative of sport harvest) compared to the sport harvest is 0.18 percent (Table 13-1). Routine and moratorium gillnetting has been conducted in JST Lake from 1986 to the present. Average catch of hybrid bass in gill nets is 617 fish/year with 69.0 percent in the desirable length category (15 inches long and longer) or 426 fish/year compared to 109 fish/year of the same length group entrained by the dam. Remarkably, like for striped bass, the effects of the baseline netting program has substantially greater impact on the numbers of larger hybrid bass than does operation of pumped storage operation under worst case conditions.

Table 13-1
JST Creel Survey Harvest Estimates Total Number By Species

YEAR	Striped Bass	Hybrid Bass	Crappie	Largemouth Bass	Yellow Perch	White Perch
1983	4,103	62,102	210,893	98,462	0	0
1984	2,568	59,384	396,190	159,526	0	0
1985	13,018	55,246	285,366	108,594	5,447	0
1986	5,691	36,016	189,311	103,878	2,350	0
1987	29,274	40,690	246,063	152,500	8,072	0
1988	No Creel					
1989	4,374	41,204	249,844	187,166	5,293	0
1990	13,531	67,195	415,446	302,137	15,438	0
1991	30,424	63,440	250,119	158,663	4,662	908
1992	11,056	77,367	252,813	209,751	3,894	4,184
1993	35,234	85,693	168,669	182,457	5,861	11,128
1994	46,525	106,591	183,994	213,489	3,633	3,900
1995	29,717	51,972	267,610	144,783	9,509	61,215
1996*	15,035	37,058	203,032	70,783	1,516	67,816
Total	240,546	783,958	3,319,350	2,092,189	65,675	149,151
AVG.	18,504	60,304	255,335	160,938	5,970	24,859

* 1996 striped bass, hybrid bass, and white perch estimates are from the South Carolina DNR creel estimates and only include the area from the confluence of the Savannah and Broad Rivers downstream to Thurmond Dam. The Georgia DNR creel estimate which includes the area from the confluence of the Savannah and Broad Rivers upstream to Russell Dam had a combined striped bass, hybrid bass, white bass, and white perch harvest of 6,564 fish, but does not include species specific estimates. All other species include a combination of both states creel estimates.

Table 13-2

Projected numbers and percentages of fish killed by entrainment during commercial pumped storage operation under dry (maximum), average, and wet (minimum) conditions and total fish numbers in JST. Total fish in JST obtained by combining arithmetic mean cove rotenone expansions (CR) excluding threadfin shad and blueback herring. Threadfin shad estimates were obtained from August 1996 mobile hydroacoustics survey (HAT). Estimates for adult blueback herring obtained from mark-recapture study (MRB). TT=cell total. Entrainment numbers based on Phase III data, April to October

¹ Population by size class determined by 5 years of cove rotenone sampling in JST Lake for species other than blueback herring and threadfin shad. Proportion of fish less than 1.2 in. determined from 1986 & 1987 cove rotenone studies and used to decrease long term mean number of fish. Threadfin shad abundance & size information obtained from mobile hydroacoustic surveys conducted in August of 1996 and blueback herring abundance obtained from May 1996 mark-recapture study.

² Numbers and percentages for Phase III expanded data based on current projections for pumping unit hours for dry, mean, and wet water years.

³ The efficiency of both the netting gear and the fixed-aspect hydroacoustics monitoring system drops off within the 2.0 in. size class (which includes fishes from 1.5 in. to 2.4 in. long).

14 Striped Bass Temperature Habitat

Summary

Water temperature and dissolved oxygen (DO) monitoring and multi-dimensional water quality modeling both indicated temperature impacts associated with pumped-storage operation in the tailwater area of RBR Dam. These impacts were coincided with a decline in striped bass and hybrid bass harvest in 1996. Water quality data collected from the critical summer period (July-September, 1992-1996) were examined to characterize tailwater and lakewide striped bass habitat dynamics in JST Lake. Water quality dynamics relative to striped bass requirements are presented because they are better known and more restrictive than hybrid bass water quality requirements.

Two categories of striped bass habitat were defined by the following bounds: preferred habitat (water having DO greater than 3.0 parts per million and temperature less than 24 °C) and restricted habitat (DO greater than 3.0 PPM and water temperature less than 27 °C). Striped bass restricted habitat in the RBR tailwater did not decrease with RBR operations in 1996 compared to conditions in 1993, a year having similar lake elevation patterns to 1996. However, a loss in striped bass preferred habitat was evident in the RBR tailwaters. The loss in preferred habitat was related to an increase in the mean water temperature released from RBR Dam and increased bottom temperatures recorded in the RBR tailwaters.

Lakewide restricted habitat did not show a noticeable decrease in 1996 compared to 1993. Lakewide preferred habitat was lowest during September, 1996, but was similar to 1993 estimates. Preferred habitat was available in other portions of the lake other than the tailwater. In 1996 water temperatures in the tailwater may have exceeded the preferred habitat criteria with a concomitant out-migration of striped bass and other cool water species into the main body of the lake. Lakewide habitat volumes estimated from the CE-QUAL-W2 water quality model indicated less habitat in years when lake levels are lower.

Introduction

Striped bass have been successfully stocked into JST Lake and provide an important and viable sport fishery. However, summer mortality of striped bass has been widely documented due to a decrease in habitat associated with a temperature-oxygen squeeze (Zale, 1990). An increase in bottom water temperatures, coupled with a decline in the striped bass harvest in the RBR tailwaters during the Phase III study, warranted further investigation into striped bass habitat in the RBR tailwaters and Strom Thurmond Reservoir. Water quality data was analyzed for the critical summer period July-August from 1992-1996 to determine if there was any change in striped bass habitat.

Methods

Striped bass habitat was broken into two categories to allow a more complete analysis. The first habitat type is termed "preferred habitat" and is defined as having an upper avoidance temperature of 24 °C and a lower dissolved oxygen avoidance concentration of 3 mg/l based on published literature (Crance, 1984; Van Den Avyle, 1990). These criteria describe the upper bonds of habitat conditions striped bass will select if made available to them. The second habitat type was termed "restricted habitat" which is defined as having an upper temperature limit of 27 °C and a lower DO concentration of 3 mg/l. Striped bass stop feeding when water temperatures reach 27 °C (Zale, 1990).

Methods used in collecting limnological data in Richard B. Russell and Strom Thurmond Reservoirs can be found in the "Water Quality and Hydrodynamics Results" section of the Phase III Report. Water quality data used in this analysis were taken from routine monthly samples throughout the lake at sampling stations as shown in Figure 2.3 of the Water Quality Phase III Report. At each station water temperature, dissolved oxygen, pH, and conductivity were measured at 2-meter intervals from the water surface to the lake bottom. The lake was divided into seven regions each containing at least one water quality station.

An elevation-volume relationship was determined for each of the seven regions based upon a digital terrain map of the lake. A regression equation was determined to approximate the elevation-volume relationship within each sub-region. A second or third order polynomial (equation 1) was found to closely fit the data in each case ($R^2 > 0.98$). The seven stations used in this analysis along with the coefficients defining the elevation-volume relationship are listed in Table 14-1. Striped bass habitat is calculated volumetrically using the CE-QUAL-W2 model

$$Vol = C1(Elev - C2)^{C3}$$

where

Vol = storage volume in cubic meters.

Elev = elevation in ft.

C1,C2,C3 = elevation volume coefficients.

A total of about 100 observations of temperature and DO were integrated over JST Lake to obtain monthly estimates of average temperature, DO, and striped bass habitat volumes listed in Tables 14-2 to 14-4. An elevation range and a corresponding volume was determined for each water quality observation. The energy or mass associated with each observation was then categorized by habitat category and totaled for the entire lake.

Results

There was no loss of restricted habitat in the RBR tailwaters during 1996 compared to previous years (Figures 1-3). However, a decline in preferred striped bass habitat was evident in the tailwater region of RBR Dam during July and August, 1996. The loss of preferred habitat in the RBR tailwaters was related to an increase in mean water temperature released from RBR Dam (Water Quality Report Figure 4.24) and increased bottom temperatures recorded in the tailwaters during 1996 compared to previous years (Water Quality Report Figures 4.6 and 4.7). Daily tailwater isotherms plotted August 23- September 2, 1996 indicate that when pump events are directly preceded by conventional generation, water temperatures decrease at all tailrace locations from PU04001 to P045 (Water Quality Report Figure 3.9).

Lakewide restricted habitat did not show a noticeable decrease in 1996 compared to 1993 (Tables 14-2 to 14-4). Similarities in limnological conditions between 1993 and 1996 were also evident in July when deeper waters near the JST Dam supported higher DO concentrations compared to other years. Restricted habitat was highest volumetrically in JST Lake during July 1994 with 68.5% of the lake available. During August, restricted habitat was highest during 1992 and 1994, respectively. The least year to year variation in restricted habitat occurred in September among the months analyzed. Higher concentrations of DO, resulting from unseasonably large discharges through JST Dam, increased striped bass habitat lakewide in September 1994 compared to other years studied.

Preferred habitat was highest during August, 1992 with 36.5% of the lake volume available. The increase in habitat during this period was mainly due to higher concentrations of DO available near the JST Dam (Figure 2). Preferred habitat was lowest volumetrically during September, 1996, but was similar to the lakewide habitat estimated in 1993.

Lake water elevation appeared to affect striped bass habitat. Higher pool elevations in 1994 during July and August could be a contributing factor to the increased volume of restricted habitat. Conversely, lower lake elevations in September of 1993 and 1996 occurred when preferred habitat was lowest.

13. ABSTRACT (Maximum 200 words) <p>The U.S. Army Engineer District, Savannah, operates Richard B. Russell (RBR) Dam and Lake which is located on the Savannah River approximately 16 miles southeast of Elberton, Georgia. RBR Lake is located between two other Federal projects: Hartwell Dam and Lake on the upstream side, and J. Strom Thurmond (JST) Dam and Lake on the downstream side. The RBR powerhouse contains four conventional generation units, and four reversible pump-turbines. The pump-turbines can be used to generate power, or they can be reversed and used as pumps to move water from JST Lake to RBR Lake during periods of low power demand to replenish upstream storage for subsequent peak generation needs.</p> <p>Potential environmental concerns associated with pump storage include entrainment of fish from the afterbay (JST Lake) during pumping, an increase in entrainment of fish from the forebay (RBR Lake) during generation resulting from generating with eight units versus four, and changes in the water quality regime of both RBR and JST Lakes.</p> <p>In view of these potential environmental concerns, the Savannah District initiated an exhaustive study in 1986, the Richard B. Russell Fish Entrainment Study. The major objectives of this study were to provide baseline data on the fish community of JST Lake, predict entrainment and fish mortality, develop fish protection measures, and monitor entrainment through the units. Ongoing water quality studies in JST and RBR Lakes were modified and expanded to supplement the fishery studies and address water quality concerns. No study identified any factor which indicated that commercial operation of the pumpback units at RBR would produce irreparable impacts to the aquatic ecosystems at RBR and JST Lakes.</p>
